Abstract

From data corresponding to an integrated luminosity of 53.5 pb^{-1} taken during the 183 GeV run in 1997, DELPHI has measured the W mass from direct reconstruction of $WW \rightarrow \ell \bar{\nu} q \bar{q}$ and $WW \rightarrow q \bar{q} q \bar{q}$ events. Combining these channels, a value of $m_W = 80.238 \pm 0.154(\text{stat}) \pm 0.035(\text{syst}) \pm 0.035(\text{fsi}) \pm 0.021(\text{LEP}) \text{ GeV}/c^2$ is obtained, where fsi denotes final state interaction.

Combined with the W mass obtained by DELPHI from the WW production cross-section and with the direct measurement at 172 GeV this leads to a measured value of $m_W = 80.270 \pm 0.137(\text{stat}) \pm 0.031(\text{syst}) \pm 0.030(\text{fsi}) \pm 0.021(\text{LEP}) \text{ GeV}/c^2$, in good agreement with the Standard Model expectation.

The width of the W boson is also measured, giving the value $\Gamma_W = 2.48 \pm 0.40(\text{stat}) \pm 0.10(\text{syst}) \text{ GeV}/c^2$. © 1999 Elsevier Science B.V. All rights reserved.

1. Introduction

During the 183 GeV run in 1997 DELPHI collected a sample of e^+e^- collisions corresponding to an integrated luminosity of 53.5 pb^{-1} . At this energy a high precision measurement of m_W can be made by reconstructing the W mass spectrum using constrained fitting techniques. This direct measurement of m_W provides an important test of the Standard Model by comparison with the indirect measurement from precise electroweak results at lower energies [1] and helps constraining the mass of the Higgs boson.

This paper describes the analysis using events in which one W decays into leptons and the other into quarks, $WW \rightarrow \ell \bar{\nu} q \bar{q}$ (“semileptonic” events), and events in which both Ws decay hadronically, $WW \rightarrow q \bar{q} q \bar{q}$ (“hadronic” events).

The paper is organised as follows. In Section 2, the DELPHI detector setup and the event generators are briefly reviewed. In Section 3, the measurement of the W mass in the semileptonic channel is presented, while Section 4 describes this measurement in the fully hadronic channel. In Section 5, the measurement of the width of the W in both channels is described. In Section 6, the combined results for

the mass and the width are presented, as well as combinations with previous DELPHI results.

2. Apparatus and simulations

Detailed descriptions of the DELPHI apparatus and its performance can be found in [2].

The response of the detector to various physics processes was modelled using the simulation program DELSIM [3], which incorporates the resolution, granularity and efficiency of the detector components. The event generator EXCALIBUR [4] was used for the simulation of all four-fermion final states (signal and background), while the background from $e^+e^- \rightarrow q \bar{q}(\gamma)$ was generated with the PYTHIA [5] event generator. For the generation of the EXCALIBUR events, the fragmentation was performed using JETSET 7.4 [6] tuned to the DELPHI LEP1 data [7], and the initial state radiation (ISR) using the QEDPS program [8]. Systematic checks were performed using other generators as described in the relevant sections.

For the signal part, a sample of 210 000 events was generated with a reference W mass of $80.35 \text{ GeV}/c^2$, while two other smaller samples of 120 000 events each were generated with masses of 79.35 and $81.35 \text{ GeV}/c^2$. At each of these masses, the simulated width was the one predicted by the standard model. The W mass and width used in this paper

¹ On leave of absence from IHEP Serpukhov.

² Now at University of Florida.

correspond to a W propagator with an s -dependent width.

3. Analysis of the semileptonic decay channel

Events were selected from the data sample recorded, requiring all detectors essential for this measurement to be fully efficient. These comprise the central tracking detectors and the electromagnetic calorimeters. The recorded sample corresponds to an integrated luminosity of 52.0 pb^{-1} .

3.1. Track selection, lepton identification and event selection

The selection of semileptonic candidates was optimized to keep events where the lepton is a muon or an electron.

Charged particles were selected if they fulfilled the following criteria:

- momentum greater than $0.2 \text{ GeV}/c$;
- impact parameter with respect to the nominal interaction point less than 4 cm (transverse) and 10 cm (longitudinal).

For neutral particles, at least one of the following selection requirements was to be fulfilled:

- energy of the shower in the electromagnetic calorimeter greater than 0.2 GeV ;
- energy of the shower in the hadron calorimeter greater than 0.5 GeV .

Charged particles were identified as muons if they were associated with a hit in the muon chambers or an energy deposition in the hadron calorimeter consistent with a minimum ionizing particle. Muon identification was performed in the polar angle range between 10° and 170° where the identification efficiency was determined from simulation to be $(92 \pm 1)\%$.

Electron identification was performed in the polar angle range between 20° and 160° by looking for charged particles with a characteristic energy deposition in the electromagnetic calorimeters. The energy was required to be within 30% of the measured track momentum or to exceed 20 GeV . In order to increase the efficiency of the selection in the forward/backward regions (below 36° and above 144°), where the momentum resolution is poorer, tracks with electromagnetic energy above 8 GeV and negligible hadron

calorimeter energy deposition were considered as electrons. Within the whole accepted region, the identification efficiency was determined from simulation to be $(77 \pm 2)\%$.

The events were selected with the same criteria as for the analysis at 172 GeV [9] except for the following:

- All neutral deposits in a cone of 3° around the muon candidate were rejected from the analysis.
- All electromagnetic clusters, not associated to a charged particle track, in a cone of 10° around the electron candidate were excluded from the jet clustering and their electromagnetic energy added to that of the electron.
- The isolation of the lepton candidate was enhanced:
 - the angle between the lepton and the nearest jet axis had to be at least 20° ;
 - the sum of the charged and of the neutral energy depositions in a cone between 10° and 15° around the electron candidate had to be less than 1 GeV .

After the selection, 88 electron and 109 muon candidates remained in the data. The number of expected events from simulation is 80.2 with a purity of 91.0% in the electron channel and 100.7 with a purity of 94.5% in the muon channel.

3.2. Kinematic reconstruction

The events were reconstructed using a constrained fit, imposing equality of the two W masses, as described in [9]. In contrast to the previous analysis, however, events were not forced into a two-jet configuration: the LUCLUS algorithm [6] (with $d_{\text{join}} = 7.5 \text{ GeV}/c$) was used to reconstruct jets once the lepton candidate had been taken out. Events with more than three jets were then reclustered, forcing them to a three-jet configuration.

The distribution of the reconstructed masses is shown in Fig. 1 for real and simulated data in the electron and muon channels.

3.3. Fitting method

The W mass was extracted from the reconstructed mass distribution using the method already used in the analysis of the data at 172 GeV [9], i.e. an event-by-event maximum likelihood fit to a relativistic

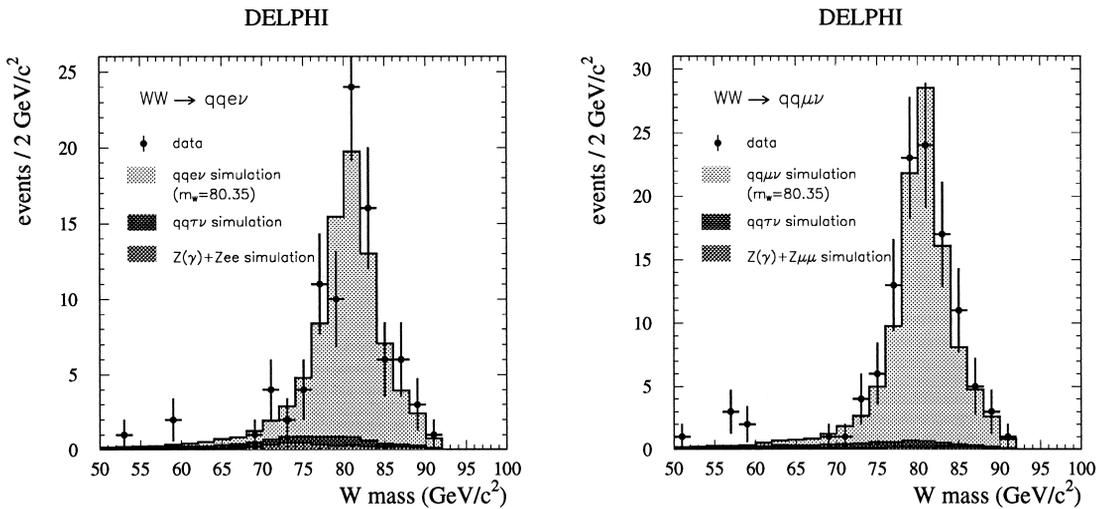

Fig. 1. The distributions of the reconstructed masses for the electron and muon channels

tic Breit-Wigner convoluted with a Gaussian resolution function plus a background distribution. The shape of the background was taken from the simulation. The error on the reconstructed mass from the constrained kinematic fit was used as the width of the Gaussian for the corresponding event. Only events in the mass range between 69 and 91 GeV/c^2 were used in the fit.

The bias from this method (shown in Fig. 2) comes mainly from the initial state radiation which is not properly taken into account in the fit, and was estimated from simulated events either generated at various input values of m_W or using a reweighting technique in order to obtain events for arbitrary

values of m_W . The bias is well described by a straight line which is used to correct the result of the likelihood fit. The error on the bias, coming from the limited statistics of the simulation, is given by the statistical error corresponding to all samples of simulated events reweighted at the measured mass. The negative slope (Fig. 2) is mainly due to ISR and reduces slightly the sensitivity of the fitted mass to the true one. The statistical error coming from the mass fit is increased accordingly.

Samples of simulated signal and background events corresponding to the integrated luminosity of the data were processed through the same mass reconstruction and fitting procedures as the real data.

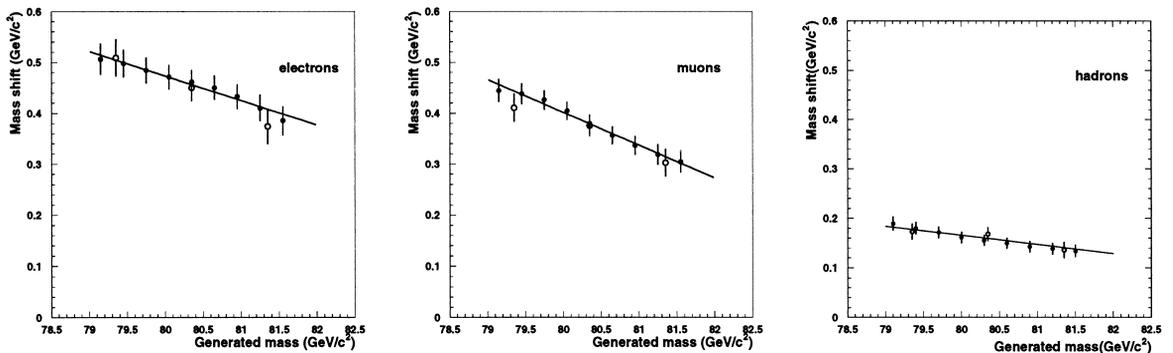

Fig. 2. Calibration curves for the mass shift (fitted mass minus generated mass) from $q\bar{q}e\nu$ (left), $q\bar{q}\mu\nu$ (centre) and $q\bar{q}q\bar{q}$ (right) events. The open circles show the mass shift computed from the individual simulated samples, while the full circles are determined from the full statistics reweighted to the corresponding mass. The error bars in the reweighted case are completely correlated and indicate the statistical error on the mass shift for a given true mass.

The pulls $(m_{\text{rec}} - m_{\text{gen}})/\sigma(m_{\text{rec}})$ obtained with these samples were used to check that the statistical error from the likelihood fit was reliable. The RMS of the pull distributions is equal to one in the electron and muon channels, with a mean expected error of 418 MeV/c² for the electrons and 331 MeV/c² for the muons.

3.4. Systematic errors

The analysis described above relies on a bias correction obtained from the simulation. Any error on the simulation will then cause a systematic error on the mass. The different sources of systematic errors are discussed in detail in [9]. The list of the relevant ones is presented in Table 1.

The statistical errors on the bias correction coming from the limited simulation statistics are 23 and 18 MeV/c², respectively, for the electron and muon channels.

Due to the presence of the neutrino in this channel, the dominant systematic effects are due to the uncertainty on the absolute energy calibrations. Bhabha and Compton scattering events showed an uncertainty on the electron energy of 1%, while the systematic uncertainty on the muon momentum was

estimated from $Z^0 \rightarrow \mu^+ \mu^-$ events to be 0.5%. This corresponds to uncorrelated systematic errors of 40 and 35 MeV/c², respectively. Jet energy uncertainty was estimated to be 2% from $Z^0 \rightarrow q\bar{q}$ events, using two-jet events where the energy is fixed and three-jet events where the energy can be estimated from angular measurement alone. The resulting systematic errors are 50 MeV/c² for the electron events and 30 MeV/c² for the muon events. The different sensitivity on the energy calibrations for the two lepton types arises because the constrained kinematic fit uses the error on the lepton energy, which is smaller for the muons than for electrons.

The impact of the background was very small in these channels, and a change of 10% in the background level led to a 5 MeV/c² change on the mass for the electrons, and a negligible one for the muons.

In order to simulate the effect of an imperfect description of the lepton acceptance in the simulation (which could induce a bias on the mass), the cut at 1 GeV on the neutral energy deposition in a cone between 5 and 15° was varied by 0.5 GeV on the simulation only and the fit was repeated. The observed shift (20 MeV/c²) was taken as the systematic error from this source.

Table 1

Contributions to the systematic error on the mass measurement. The error sources have been separated into those uncorrelated and correlated between the different LEP experiments.

Sources of systematic error (MeV/c ²)	$e\bar{\nu}q\bar{q}$	$\mu\bar{\nu}q\bar{q}$	$l\bar{\nu}q\bar{q}$	$q\bar{q}q\bar{q}$	Combined

LEP energy	21	21	21	21	21
Colour reconnection	–	–	–	50	33
Bose Einstein correlations	–	–	–	20	13
Total final state interaction	–	–	–	54	35

The uncertainty coming from the modelling of the initial state radiation in the simulation was estimated by comparing the distribution of the energy lost by ISR in events simulated with our EXCALIBUR generator and in events simulated with the KORALW generator [10]. The agreement was found to be very good, and an uncertainty of $10 \text{ MeV}/c^2$ was derived.

When fitting the mass of the W, the width of the Breit-Wigner was fixed. The chosen value has no importance as it led to negligible changes on the fitted mass, and is anyway corrected for by the calibration curve. What is more relevant here is the value of the width which has been used for the generation of the simulated events. The simulated events have been reweighted in order to reproduce a shift of one standard deviation on the world average measurement of the width ($60 \text{ MeV}/c^2$ [11]) and the whole procedure was repeated. The resulting effect on the measured mass was found to be negligible.

For the lepton combination, all sources of systematic errors are taken as uncorrelated between electron and muon, except for the errors coming from the jet energy, the fragmentation and the ISR which are taken as fully correlated.

3.5. Results

The event-by-event likelihood analysis on the semileptonic channels gave the following results:

$$m_W = 80.612 \pm 0.431(\text{stat}) \pm 0.072(\text{syst}) \\ \pm 0.021(\text{LEP}) \text{ GeV}/c^2$$

for electron events and

$$m_W = 80.462 \pm 0.341(\text{stat}) \pm 0.052(\text{syst}) \\ \pm 0.021(\text{LEP}) \text{ GeV}/c^2$$

for muon events. The last error ³ comes from the uncertainty on the beam energy (25 MeV [12]).

The combination of the two gives the following result:

$$m_W = 80.520 \pm 0.267(\text{stat}) \pm 0.051(\text{syst}) \\ \pm 0.021(\text{LEP}) \text{ GeV}/c^2.$$

4. Analysis of the hadronic decay channel

The present analysis is largely based on the analysis used by DELPHI to extract the W mass from the 172 GeV data [9]. It is also an event-by-event likelihood method, taking into account all jet-pairings. However, in contrast to the analysis of [9], the masses of the two W bosons are not assumed to be equal. Instead, the W mass is extracted using a two-dimensional ideogram likelihood method.

Requiring only that the central tracking was fully efficient, events were selected from a data sample corresponding to an integrated luminosity of 52.9 pb^{-1} .

4.1. Event selection

In the fully hadronic channel, emphasis was put on obtaining a high efficiency for $WW \rightarrow q\bar{q}q\bar{q}$ events that contain useful information about the W mass. Obtaining a high purity in the selected sample was considered to have a lower priority, because the background from two-fermion processes is taken into account by an estimated event-by-event purity later in the analysis, and the contribution from hadronic ZZ events is included as a separate term in the likelihood expression (see Section 4.3). Instead the selection was designed to be minimally biased by the mass information contained in the event. The following selection criteria were used:

- Events were required to have at least 14 reconstructed tracks;
- A visible energy of more than $1.15 E_{\text{beam}}$ was required;
- At least four jets had to be reconstructed using the Durham [13] algorithm with $y_{\text{cut}} = 0.001$;
- On forcing the event into a four-jet configuration, each jet had to have at least three particles and an invariant mass larger than $1 \text{ GeV}/c^2$;

³ $\Delta m_W / m_W \approx \Delta E_{\text{beam}} / E_{\text{beam}}$

- The invariant mass of the whole jet system, excluding isolated high energy photons inside the detector and estimated by doing a constrained kinematic fit assuming that there was one (additional) photon of unknown energy radiated into the beampipe, had to be larger than $150 \text{ GeV}/c^2$.

The efficiency and purity (with respect to WW events) of this selection were estimated to be 88% and 66% respectively. A total of 540 events were selected from the data (see Fig. 3). The number of events expected from simulation was 518.

4.2. Kinematic reconstruction

A constrained fit [9] was used to obtain optimal precision on the 4-momenta of the jets.

In the fully hadronic channel there are three possible jet-pairings when there are four jets, and 10 in a five-jet event. Events with more than five jets were forced into a five-jet configuration. For every possible jet-pairing, the probability density function $p_i(m_x, m_y)$ that this pairing corresponds to two objects with masses m_x and m_y was computed: a fit with constraints from energy and momentum conservation was performed, fixing the two masses to m_x and m_y , and the probability p_i was derived from the resulting χ^2 as $p_i(m_x, m_y) \propto \exp(-\frac{1}{2}\chi_i^2(m_x, m_y))$.

The different jet-pairings are equivalent from the point of view of goodness-of-fit. However, jet-pairings that have a small difference between the two fitted masses will naturally have a larger impact on the W mass likelihood (see Section 4.3), due to the limited decay width of the W boson. In order to improve the jet-pairing further without biasing the mass, relative probabilities were calculated that a jet-pairing is the correct one. This was done in the following way:

- The measured jet charges⁴ were used to determine the probability for a proposed W boson to be a W^+ or a W^- . From this probability, a relative weight was calculated corresponding to the production angle, assuming a flat distribution for the combinatorial background.
- For 5-jet events, the most probable gluon jet candidate in every jet-pairing was chosen from the 3 jets supposed to belong to one W boson by taking the jet with the lowest transverse momentum, k_t , with respect to the other two jets in the rest-frame of the W boson. The relative weight for that jet-pairing was then multiplied by the probability $p \propto 1/k_t$ to emit a gluon with the observed transverse momentum.

Using these weights, the $p_i(m_x, m_y)$ distributions were added in a weighted sum. Thus for every event a probability density function was obtained containing all the extracted mass information from the kinematics of the event. This so-called two-dimensional probability ideogram reflects the relative compatibility of the kinematics of the event with the hypothesis that two heavy objects with the corresponding masses m_x, m_y were produced, with a $1/k_t$ gluon emission spectrum and a production angle distributed like in W^+W^- events. Examples are shown in Fig. 4.

In order to reduce the contribution from events with poorly reconstructed jets, this procedure was repeated with two other jet algorithms (CAMJET [14] and DCLUS [15]). The number of jets was fixed to the number found with the DURHAM algorithm. The three ideograms were then simply added

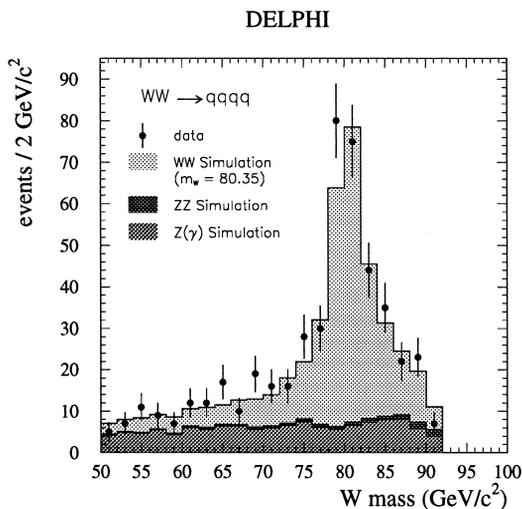

Fig. 3. Mass plot for the selected $WW \rightarrow q\bar{q}q\bar{q}$ candidates showing only one reconstructed mass per event (that with the best χ^2), and using an equal-mass constraint (not used in the determination of m_W , see text).

⁴ The jet charges were computed as the weighted charge of particles in the jet, with a weight proportional to the square root of the longitudinal momentum.

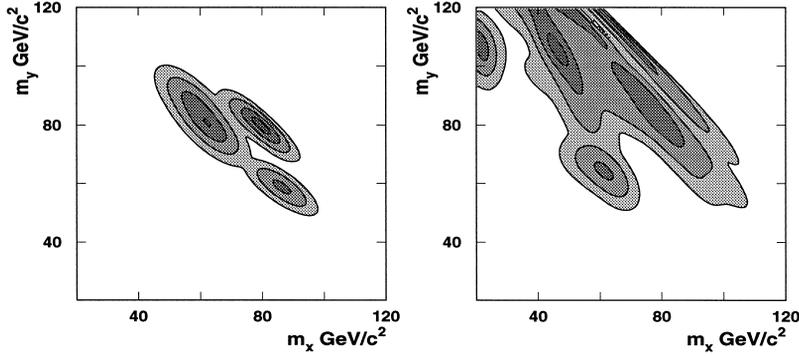

Fig. 4. Examples of two-dimensional probability ideograms for a 4-jet (left) and 5-jet (right) hadronic event. The first 4 sigma contours are shown.

with equal weights. Events with ambiguous clustering give combined ideograms with broader resolutions. This allowed us to reduce the overall jet errors in the constrained fit by 20%. This procedure reduced the expected statistical error on m_W by 4%.

4.3. Event-by-event likelihood

For every event the likelihood $\mathcal{L}_e(m_W, \Gamma_W)$ of the W mass and width was calculated using

$$\begin{aligned} \mathcal{L}_e(m_W, \Gamma_W) = & \int \sum_i p_{i,e}(m_x, m_y) \\ & \times \left\{ P_e^{\text{eff}} \cdot S(m_x, m_y, m_W, \Gamma_W) \right. \\ & \left. + (1 - P_e^{\text{eff}}) \cdot B(m_x, m_y) \right\} dm_x dm_y \end{aligned}$$

where $S(m_x, m_y, m_W, \Gamma_W)$ is the probability that a mass combination m_x, m_y is produced in a 4-fermion event, $B(m_x, m_y)$ the corresponding distribution for the background processes, and P_e^{eff} the estimated effective purity of the event, i.e. the probability that the event is a well-clustered fully hadronic 4-fermion event. The significant contributions to $S(m_x, m_y, m_W, \Gamma_W)$ are from resonant WW and ZZ production; all other contributions, including the interference between these two resonant processes, were found to be negligible. These two contributions were weighted according to their accepted cross-sections:

$$\begin{aligned} S(m_x, m_y, m_W, \Gamma_W) & \\ = & \frac{\sigma_{\text{WW}}^{\text{acc}}}{\sigma_{\text{WW}}^{\text{acc}} + \sigma_{\text{ZZ}}^{\text{acc}}} \cdot S_{\text{WW}}(m_x, m_y, m_W, \Gamma_W) \\ & + \frac{\sigma_{\text{ZZ}}^{\text{acc}}}{\sigma_{\text{WW}}^{\text{acc}} + \sigma_{\text{ZZ}}^{\text{acc}}} \cdot S_{\text{ZZ}}(m_x, m_y, m_Z, \Gamma_Z) \end{aligned}$$

where $S_{\text{WW}}(m_x, m_y, m_W, \Gamma_W)$ and $S_{\text{ZZ}}(m_x, m_y, m_Z, \Gamma_Z)$ were approximated by the product of two relativistic Breit-Wigner functions and a phase-space correction factor $\text{PS}(m_x, m_y)$

$$\text{PS}(m_x, m_y) \propto \frac{\sqrt{(s - m_x^2 - m_y^2)^2 - 4m_x^2 m_y^2}}{s}$$

and both $S_{\text{WW}}(m_x, m_y, m_W, \Gamma_W)$ and $S_{\text{ZZ}}(m_x, m_y, m_Z, \Gamma_Z)$ were normalized to one over the integration area. The background function $B(m_x, m_y)$ was taken to be proportional to the same phase-space correction function $\text{PS}(m_x, m_y)$. Monte Carlo simulation shows that this is a good approximation.

To obtain the effective event purity P_e^{eff} , the signal-to-(signal + background) ratio was parametrized as a function of a discriminating variable $D_{\text{pur}} = \theta_{\text{min}} \cdot E_{\text{min}}$, where θ_{min} is the smallest angle between any two jets, and E_{min} the lowest jet energy (see Fig. 5). In this calculation fully hadronic ZZ events are treated as signal and $Z\gamma$ events as background. This purity was multiplied by a factor $\epsilon_{\text{cluster}}$, estimating the fraction of the events in which the clustering algorithm succeeds in separating the jets correctly. Both in the four-jet and five-jet cases, $\epsilon_{\text{cluster}} (= 0.80)$ was determined from a global tuning where the jet errors (in the kinematic fit) and $\epsilon_{\text{cluster}}$ were adjusted so that the width of the pull distribution (see end of this section) should be equal to unity and the bias on the W width determination (see Section 5) minimized. This efficiency was cross-checked with simulated events from the distribution of the quantity $\chi^2(m_x^{\text{gen}}, m_y^{\text{gen}}) - \chi_{\text{min}}^2(m_x, m_y)$ where $\chi^2(m_x^{\text{gen}}, m_y^{\text{gen}})$ and $\chi_{\text{min}}^2(m_x, m_y)$ are ob-

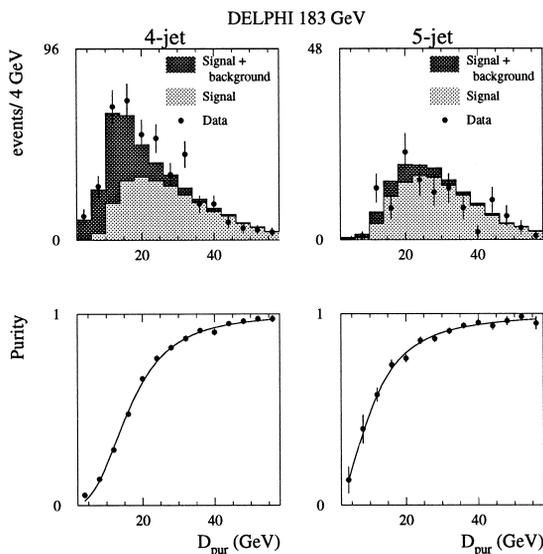

Fig. 5. Parameterisation of the purity per event: the top plots show the distribution of $D_{\text{pur}} = E_{\text{min}} \theta_{\text{min}}$ for data and simulated events in four-jet (left) and five-jet (right) configurations, after applying all event selection cuts; the bottom plots show the parametrization of the purity per event as a function of D_{pur} obtained from the simulated events.

tained, respectively, from kinematic fits with m_x and m_y at their generated values and at the values giving the best fit to the event. This quantity is expected to follow a χ^2 distribution with two degrees of freedom, but, in practice, 20% of events are found to lie in a tail with too high values.

As the candidate events are not correlated, the combined likelihood is the product of all the event likelihoods.

The bias from this method (shown in Fig. 2) as a function of the true W mass was determined using the three simulated samples with different input values for the generated W mass. As in Section 3.3, a linear dependence was fitted and used to correct the result of the likelihood fit.

In order to check if the statistical error obtained from the likelihood curve is a good estimator, pull distributions were studied using one million samples of simulated events. The samples were composed from simulated events generated with $m_W = 80.35 \text{ GeV}/c^2$ and according to Poissonian statistics corresponding to the expected number of signal and background events. The mean RMS of the pull distri-

bution as a function of the estimated error is compatible with unity within 2%, which means that the error obtained from the likelihood curve is a reliable estimate of the statistical error on the W mass. The mean expected error was $193 \text{ MeV}/c^2$.

4.4. Systematic errors

The calibration of the analysis depends on the accuracy of the simulation. Errors in the simulation can lead to systematic shifts of the measured W mass. Table 1 shows the estimated systematic errors coming from possible inaccuracies in the simulation.

The statistical error on the bias correction, coming from the limited simulation statistics, is $9 \text{ MeV}/c^2$. The uncertainty coming from the jet energy calibration is much reduced compared to the semileptonic case because of the absence of missing energy. It corresponds to a $20 \text{ MeV}/c^2$ error. The systematic error coming from the background level has been estimated by changing its amount by 10%, while the uncertainty from the shape of the background mass distribution has been taken from the difference between the two Monte Carlo generators JETSET [6] and ARIADNE [16]. Both lead to a $5 \text{ MeV}/c^2$ systematic error. The impact of an incorrect description of the jet fragmentation has been studied by using WW events simulated with two different treatments of the parton shower (JETSET and ARIADNE). The difference was compatible with zero with a $20 \text{ MeV}/c^2$ statistical error which was taken as the systematic error from this source.

Since the two Ws under LEP2 conditions decay much closer to each other than the typical hadronization scale of $0.5 - 1.0 \text{ fm}$, interactions among the decay products in fully hadronic events may lead to systematic shifts of the reconstructed W mass. Two possible sources of such effects have been identified: colour reconnection among partons from the two different colour singlet systems [17] and Bose-Einstein correlations among identical bosons in the final state [18]. Colour reconnection during the perturbative phase of the parton shower evolution has been shown to give rise to mass shifts below $5 \text{ MeV}/c^2$ and is neglected here. Colour reconnection in the non-perturbative phase has been described in a number of phenomenological models, which are implemented in several Monte Carlo generators [6,16,19].

Whereas the expected error on the W mass from a first round of comparisons of models [20] was estimated to be around $50 \text{ MeV}/c^2$, more recent studies [21] indicate that with the present mass reconstruction methods, the effect may be much smaller.

The effect was tested using two variants of the ARIADNE model. In the first variant (AR2), only gluons with energies less than Γ_W are allowed to reconnect, whereas the second variant (AR3) allows also reconstructions of gluons with higher energy. Since colour reconnection in the perturbative phase is expected to be suppressed [17], the latter model is theoretically disfavoured and will not be used in the estimate of the systematic error on the W mass. The fast DELPHI detector simulation program [22] was used together with the event selection and mass reconstruction procedure above. The observed mass shifts were $28 \pm 6 \text{ MeV}/c^2$ for AR2 and $55 \pm 6 \text{ MeV}/c^2$ for AR3. Since other viable models of colour reconnection have not yet been investigated in studies specific to the present experiment, a systematic error in the W mass of $50 \text{ MeV}/c^2$ is conservatively assigned for this effect.

The effect of Bose-Einstein correlations on the measured W mass has also been the subject of a number of recent phenomenological studies [23–26], which indicate that the shift is likely to be at most $20 - 30 \text{ MeV}/c^2$ and possibly even smaller [27]. For the present paper this was tested in two detector specific studies in which the same event selection and mass reconstruction method as for the real data were used.

The first study was based on one of the global event weight schemes [24]⁵ and used the EXCALIBUR Monte Carlo sample with $m_W = 80.35 \text{ GeV}/c^2$ described above. In the second study a Bose-Einstein simulation code [27] was used, which is based on a modification of the JETSET fragmentation to include quantum mechanical interference effects among two or three identical bosons. The resulting shifts of the reconstructed W mass were $-10 \pm 10 \text{ MeV}/c^2$ and $0 \pm 10 \text{ MeV}/c^2$, respectively. The models were not retuned, however, and a systematic error on the W mass of $20 \text{ MeV}/c^2$ due to Bose-Einstein correlations is assigned.

The combined systematic error on the W mass measured in the fully hadronic channel from final state interactions is thus estimated to be at most $54 \text{ MeV}/c^2$.

4.5. Result for the hadronic channel

The two-dimensional ideogram analysis on the hadronic channel gave the following result:

$$m_W = 80.097 \pm 0.189(\text{stat}) \pm 0.032(\text{syst}) \\ \pm 0.054(\text{fsi}) \pm 0.021(\text{LEP}),$$

where ‘fsi’ denotes the possible effect from final state interactions and ‘LEP’ the uncertainty on the beam energy.

4.6. Cross-check by an independent algorithm

The W -boson mass was also measured in the fully hadronic channel by a different and independent method. A neural network was used to tag the signal, leading to an efficiency and purity of 85% and 80% respectively. The number of events selected from the data was 401, while 398 events were expected from studies performed on simulated events. In the mass reconstruction procedure, the jet multiplicity was left free to vary between four and eight jets. A fast kinematic fit was applied to improve the mass resolution of multijet events by imposing momentum and energy conservation while the directions of the jets were left unchanged. Events with more than five jets were forced into a five-jet configuration for both the kinematic fit and jet pairing stage.

The jet assignment was also performed using a neural network algorithm. For each combination, the interjet angles and the difference between the two reconstructed masses discriminate between the different clustering solutions. To reduce the bias arising from a single generated mass, the neural network was trained with W boson masses uniformly spread in the range $75 < m_W < 86 \text{ GeV}/c^2$.

The W boson mass was extracted from a likelihood fit to the two-dimensional plot formed by the average and the difference of the two W -masses, using the distribution predicted by the full simulation. In order to obtain the simulated spectrum for arbitrary values of m_W , a Monte Carlo reweighting technique was used as in Section 3.3. A binned log-likelihood fit to the data was then performed which avoids the analytical parametrization of the

⁵The weight function V_3 in [24] was used.

Table 2
Dominant contributions to the systematic error on Γ_W .

Sources of systematic error (MeV/c ²)	$e\bar{\nu}q\bar{q}$	$\mu\bar{\nu}q\bar{q}$	$l\bar{\nu}q\bar{q}$	$q\bar{q}q\bar{q}$	Combined

Total	83	72	57	135	100

shapes. As the final states with jet multiplicities of four, five, and above have very different mass resolutions, the overall likelihood was the sum of three independent likelihoods, evaluated with the two-dimensional Monte Carlo probabilities relevant to each class of final states. The mass value and the statistical error obtained from this likelihood fit to the data are $m_W = 80.126 \pm 0.183 \text{ GeV}/c^2$, in good agreement with the results quoted in Section 4.5. The expected statistical error from the simulated events is $215 \text{ MeV}/c^2$ and has been checked with samples of the same statistics as the data, using the technique described in Section 4.3. The systematic uncertainties are common to the previous analysis, except for that due to the background shape. It is estimated to be around $15 \text{ MeV}/c^2$ with an alternative fragmentation scheme (HERWIG instead of JETSET). The event-by-event likelihood analysis has been taken as the reference analysis because it gave the smaller expected error.

5. Width of the W boson

The same unbinned likelihood analyses (described in Section 3.3 for the semileptonic channel and in Section 4.3 for the hadronic one) were applied in order to measure the width of the W boson, fixing the mass and varying the width in the likelihood fit. A linear calibration curve was also used to correct the result from the fits. For this calibration curve, the Monte Carlo events have been reweighted to the mass of $80.35 \text{ GeV}/c^2$, for different values of the width. The correlation between m_W and Γ_W was found to have a negligible impact.

The centre-of-mass energy spread has been measured [12] and is about 220 MeV. Its impact on the width measurement is negligible. The dominant sources of systematic errors are presented in Table 2.

For the semileptonic channels, the results are

$$\Gamma_W = 2.09 \pm 1.10(\text{stat}) \pm 0.08(\text{syst}) \text{ GeV}/c^2$$

for electrons,

$$\Gamma_W = 3.61 \pm 1.05(\text{stat}) \pm 0.07(\text{syst}) \text{ GeV}/c^2$$

for muons,

which give, when combined,

$$\Gamma_W = 2.89 \pm 0.76(\text{stat}) \pm 0.06(\text{syst}) \text{ GeV}/c^2,$$

while the hadronic channel gives

$$\Gamma_W = 2.33 \pm 0.47(\text{stat}) \pm 0.14(\text{syst}) \text{ GeV}/c^2.$$

6. Combination of all results

The masses measured in the semileptonic and hadronic decays analysis are in good agreement within statistics. Combining them yields

$$m_W = 80.238 \pm 0.154(\text{stat}) \pm 0.035(\text{syst}) \\ \pm 0.035(\text{fsi}) \pm 0.021(\text{LEP}) \text{ GeV}/c^2.$$

Our previous measurements derived from the cross-section [28] ($m_W = 80.49 \pm 0.43(\text{stat}) \pm 0.09(\text{syst}) \pm 0.03(\text{LEP}) \text{ GeV}/c^2$) and from our 172 GeV data [9] ($m_W = 80.22 \pm 0.41(\text{stat}) \pm 0.04(\text{syst}) \pm 0.03(\text{fsi}) \pm 0.03(\text{LEP}) \text{ GeV}/c^2$)⁶ are fully compatible with this more precise value. Combining all these measurements of the W mass yields

⁶ Our present estimate of the fsi error has been applied to the 172 GeV data.

$$m_W = 80.270 \pm 0.137(\text{stat}) \pm 0.031(\text{syst}) \\ \pm 0.030(\text{fsi}) \pm 0.021(\text{LEP}) \text{ GeV}/c^2.$$

The width of the W has been measured. Combining results from the semileptonic and hadronic decay modes yields

$$\Gamma_W = 2.48 \pm 0.40(\text{stat}) \pm 0.10(\text{syst}) \text{ GeV}/c^2.$$

Acknowledgements

We are greatly indebted to our technical collaborators, to the members of the CERN-SL Division for the excellent performance of the LEP collider, and to the funding agencies for their support in building and operating the DELPHI detector. We acknowledge in particular the support of Austrian Federal Ministry of Science and Traffics, GZ 616.364/2-III/2a/98, FNRS–FWO, Belgium, FINEP, CNPq, CAPES, FUJB and FAPERJ, Brazil, Czech Ministry of Industry and Trade, GA CR 202/96/0450 and GA AVCR A1010521, Danish Natural Research Council, Commission of the European Communities (DG XII), Direction des Sciences de la Matière, CEA, France, Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie, Germany, General Secretariat for Research and Technology, Greece, National Science Foundation (NWO) and Foundation for Research on Matter (FOM), The Netherlands, Norwegian Research Council, State Committee for Scientific Research, Poland, 2P03B06015, 2P03B1116 and SPUB/P03/178/98, JNICT–Junta Nacional de Investigação Científica e Tecnológica, Portugal, Vedecka grantova agentura MS SR, Slovakia, Nr. 95/5195/134, Ministry of Science and Technology of the Republic of Slovenia, CICYT, Spain, AEN96–1661 and AEN96-1681, The Swedish Natural Science Research Council, Particle Physics and Astronomy Research Council, UK, Department of Energy, USA, DE–FG02–94ER40817.
