Abstract. Soft photons inside hadronic jets converted in front of the DELPHI main tracker (TPC) in events of $q\overline{q}$ disintegrations of the Z^0 were studied in the kinematic range $0.2 < E_\gamma < 1\,\mathrm{GeV}$ and transverse momentum with respect to the closest jet direction $p_\mathrm{T} < 80\,\mathrm{MeV/c}$. A clear excess of photons in the experimental data as compared to the Monte Carlo predictions is observed. This excess (uncorrected for the photon detection efficiency) is $(1.17 \pm 0.06 \pm 0.27) \times 10^{-3}\,\gamma/\mathrm{jet}$ in the specified kinematic region, while the expected level of the inner hadronic bremsstrahlung (which is not included in the Monte Carlo) is $(0.340 \pm 0.001 \pm 0.038) \times 10^{-3}\,\gamma/\mathrm{jet}$. The ratio of the excess to the predicted bremsstrahlung rate is then $(3.4 \pm 0.2 \pm 0.8)$, which is similar in strength to the anomalous soft photon signal observed in fixed target experiments with hadronic beams.

1 Introduction

Electromagnetic radiation in the soft photon region arising from interacting hadrons is assumed to be well understood theoretically. In classical papers by Landau and Pomeranchuk [1] and Low [2] it has been shown that the main source of soft photons in hadron reactions is the internal hadronic bremsstrahlung, i.e. the bremsstrahlung radiation from the initial and final hadronic states. Later, Gribov [3] defined quantitatively the meaning of the term soft photon as applied to high energy hadron reactions: the transverse momentum, p_T, of such a photon has to be small as compared to typical values of this variable for secondary particles produced in these reactions, which are 300–$400\,\mathrm{MeV/c}$.

The experimental investigation of soft photon production in hadron interactions at high energy started with the bubble chamber experiment [4] at SLAC in which photons from the reaction $\pi^+ p \rightarrow \gamma + X$ at an incident momentum of $10.5\,\mathrm{GeV/c}$ were studied. A signal consistent at the 30% probability level with the expectations for the inner hadronic bremsstrahlung was found. The result was considered as a confirmation of theoretical predictions for soft photon production.

However in the next experiment, carried out by the WA27 Collaboration at CERN using the BEBC bubble chamber, a clear soft photon signal in excess of the inner bremsstrahlung prediction was reported for a $K^+ p$ exposure at $70\,\mathrm{GeV/c}$ [5]. After subtraction of photons coming from all known hadronic decays the residual signal was found to be similar in shape to bremsstrahlung but larger in size by a factor of about four in the p_T region below $60\,\mathrm{MeV/c}$. Then results from the CERN experiment NA22 with K^+ and π^+ beams on protons at $250\,\mathrm{GeV/c}$ also demonstrated an excess of soft photons in a similar kinematic region by a factor of 5 to 7 as compared to bremsstrahlung predictions [6]. Similar effects were found later in the experiment WA83 where a fine-grained forward electromagnetic calorimeter was used to detect photons produced in $\pi^- p$ interactions at $280\,\mathrm{GeV/c}$ [7], and again in the experiment WA91 which also used $\pi^- p$ interactions at $280\,\mathrm{GeV/c}$, but implemented a different technique for the detection of photons by reconstruction of $e^+ e^-$ pairs from photon conversion in a thin lead sheet placed in front of the OMEGA spectrometer tracker [8].

The situation is less clear with a proton projectile. Experiment E855 at BNL with protons at $18\,\mathrm{GeV/c}$ on Be and W targets did not find any signal of direct soft photons at central and slightly backward rapidities, imposing an upper limit for such photons at 2.7 times the hadronic bremsstrahlung [9]. In a similar photon kinematic region, the experiment HELIOS at CERN with proton projectiles at $450\,\mathrm{GeV/c}$ on a Be target found a direct soft photon signal compatible with the expected hadronic bremsstrahlung, and derived an upper limit on the presence of additional sources of direct soft photons of about a factor of two relative to the bremsstrahlung [10]. Recently, the signal of direct soft photons at the level of four times the bremsstrahlung predictions was observed at forward rapidities in pp interactions at $450\,\mathrm{GeV/c}$ in the CERN experiment WA102 [11]. Note, in the latter paper a summary of experimental results on direct soft photon observations, including kinematic ranges of particular experiments, is also given[1].

Generalizing the results of the experiments which observed an excess of soft photons, it can be concluded that the photon distributions, studied in the very forward region, were reported to be roughly similar in shape to that expected for the inner hadronic bremsstrahlung calculated from QED, but the observed photon rates were several times larger than expected. Owing to this enhancement factor the observed excess photons were dubbed *anomalous*.

Meanwhile various theoretical models [13-33] were suggested, aimed at explaining the effect of anomalous photons by introducing new phenomena into the soft physics of hadronic interactions. Some of them were able to describe some particular features of the experimental data, by interpreting anomalous soft photons as a radiation from a cold quark-gluon plasma [13, 17, 22], a transient new coherent condition of matter [14, 24–26], or as a synchrotron radiation from quarks [27–29] in the stochastic QCD vacuum [34]. However, no model was able to describe the experimental data satisfactorily as a whole, especially in a kinematic range where the effect was most prominent (for a review of the theoretical approaches see [16, 22]).

In this situation extending the class of reactions in which the phenomenon of anomalous soft photons is inves-

---

[1] In addition, an excess of soft photons with $E_\gamma < m_\pi c^2/2$ has been also observed in $\overline{p}p$ interactions at $32\,\mathrm{GeV/c}$ [12], however it was not compared with bremsstrahlung predictions.

tigated has become of interest. This motivated us to study the reaction

$$e^+e^- \to Z^0 \to \text{hadrons} \qquad (1)$$

at LEP1 searching for extra photons in hadronic decays of Z^0 bosons.

Several studies of photon production in hadronic Z^0 decays have been carried out by all the LEP experiments [35–44] including searches for anomalous photon radiation from non-Standard Model sources [35, 39, 41]. The latter aimed at finding photons emitted by a non-standard source or by quarks before or at the beginning of the fragmentation process. Therefore a signal of rather hard photons well separated from other tracks was searched for. In contrast, the current analysis deals with soft photons deep inside jets, with the aim to separate a signal of soft photons coming from the inner hadronic bremsstrahlung (mainly from the final hadronic states) or from unknown photon sources responsible for the anomalous soft photon radiation seen in hadronic experiments. The photon softness can be characterized in this case by a value of the transverse momentum of a photon with respect to the closest jet. We shall use the term p_T for this variable throughout this article. The p_T range chosen to be studied in this work extends from 0 to 80 MeV/c, while searches for anomalous photons carried out so far in LEP experiments required them to be hard and isolated ($E_\gamma > 5$ GeV, in general, and at angles to the closest jet $> 20°$), thus at $p_T > 1.7$ GeV/c, i.e. well outside our kinematic region.

This paper is organised as follows. Section 2 provides a description of the apparatus, software, and the experimental method applied. This section also includes a description of selection cuts and data samples. Systematic uncertainties arising from various elements of the analysis method, and their estimates are presented in Sect. 3. Section 4 deals with the calculation of the inner hadronic bremsstrahlung and its systematic errors. In Sect. 5 the main results of the analysis are given, both uncorrected and corrected for the detection efficiency. The results show an excess of soft photons in the real data as compared to the Monte Carlo predictions. Section 6 is devoted to the study of possible systematic biases capable of imitating this excess. Finally, Sect. 7 provides a summary and conclusions.

2 Experimental technique and data selection

2.1 The DELPHI detector

The DELPHI detector is described in detail elsewhere [45, 46]. The following is a brief description of the sub-detector units relevant for this analysis. In the DELPHI reference frame the Z axis is taken along the direction of the e^- beam. The angle Θ is the polar angle defined with respect to the Z-axis, Φ is the azimuthal angle about this axis and R is the distance from this axis.

The DELPHI barrel tracking system relied on the vertex detector (VD), the inner detector (ID), the time projection chamber (TPC) and the outer detector (OD). The

barrel electromagnetic calorimeter, the high density projection chamber (HPC) lay immediately outside the tracking detectors. It was used in this analysis for cross-checks only. All these detectors were embedded in a superconducting solenoidal coil providing a uniform magnetic field of 1.23 T, aligned parallel to the beam axis.

The TPC, the principal device used in this analysis, was the main tracker of the DELPHI detector; it covered the angular range from $20°$ to $160°$ in Θ and extended from 30 cm to 122 cm in R. It provided up to 16 space points for pattern recognition and ionization information extracted from 192 wires.

The HPC covered the angles Θ from $43°$ to $137°$. It had eighteen radiation lengths for perpendicular incidence, and its energy resolution was $\Delta E/E = 0.31/E^{0.44} \oplus 0.027$ where E is in units of GeV [47]. It had a high granularity and provided a sampling of shower energies from nine layers in depth. The angular precisions for high energy photons were ± 1.0 mrad in Θ and ± 1.7 mrad in Φ.

2.2 Software

The principal Monte Carlo (MC) data sets used in this analysis were produced with the JETSET 7.3 PS generator [48] with parameters adjusted according to previous QCD studies [49, 50]. For the test of possible systematic biases, two other standard generators: ARIADNE 4.6 [51] and HERWIG 5.8C [52] with parameters adjusted by the DELPHI tuning [50] were also used.

No generation of bremsstrahlung photons from final state hadrons was implemented in the MC generators. On the other hand, the initial state radiation (ISR) and photon radiation from quarks of Z^0 disintegrations were produced using the DYMU3 generator [53] and photon implementation in JETSET [54]. However, as will be shown in Sect. 4, the soft photon rates from these sources are very small as compared to the bremsstrahlung from final state hadrons and therefore need not be considered further.

The generated events were fed into the DELPHI detector simulation program DELSIM [46] in order to produce data which are as close as possible to the real raw data. These data were then treated by the reconstruction and analysis programs in exactly the same way as the real data.

To reconstruct jets, the LUCLUS code [55] with a fixed resolution parameter $d_{\text{join}} = 3$ GeV/c was used. To check the stability of the obtained results, the jet-finding algorithms DURHAM [56] and JADE [57] were also used, both with the resolution parameter $y_{\text{cut}} = 0.01$. The minimal number of jets in the event was required to be two.

2.3 Identification of soft photons

As has already been said, the anomalous soft photon production was observed in hadronic reactions at small p_T and small polar angles relative to an incident hadronic beam. In $q\bar{q}$ disintegrations of the Z^0 the corresponding "beam" direction is represented by the direction of the initial q and/or $\bar{q}$ and thus the photon angle θ_γ defined with respect to the parent jet axis is taken as the angular variable in our

study, with p_T being the photon momentum projected onto the plane perpendicular to that axis. The requirement for the kinematic range to correspond to that of hadronic reactions (small p_T, small θ_γ angles) prevents the use of the DELPHI electromagnetic calorimeters for the detection of soft photons due to the strong pile-up of hard photons hitting the calorimeters near the jet axis.

Fortunately for the aim of this analysis, the DELPHI setup contains a significant amount of material in front of the sensitive volume of the DELPHI main tracker, the TPC. About 7% of all photons in the barrel region are converted in front of the tracker. These photons produce in general two reconstructible e^+e^- tracks in the TPC, giving rise to a clean and well defined photon sample which is used in this analysis.

The energy threshold for the reconstruction of these photons is 0.2 GeV. This, together with the upper cutoff of 1 GeV usually applied in soft photon studies, defined the energy range to be investigated, $0.2 < E_\gamma < 1$ GeV. Since the study of such photons is not typical in the LEP experiments, we present the characteristics of their detection in detail, starting with a description of the algorithm for the reconstruction of converted photons from tracks detected in the TPC.

A search was made along each TPC track for points where the tangent of its trajectory points directly to the beam spot in the $R\Phi$ projection. Under the assumption that the opening angle of the electron–positron pair is zero, this point represented a possible photon conversion point at radius R. All tracks which have had a solution R that was more than one standard deviation away from the main vertex, as defined by the beam spot, were considered to be conversion candidates. If two oppositely charged conversion candidates were found with compatible conversion point parameters they were linked together to form the converted photon. The following selection criteria were imposed:

– the Φ difference between the two conversion points was at most 30 mrad;
– the difference between the polar angles Θ of the two tracks was at most 15 mrad;
– at least one of the tracks should have no associated point in front of the reconstructed mean conversion radius.

For the pairs fulfilling these criteria a χ^2 was calculated from $\Delta\Theta$, $\Delta\Phi$ and the difference of the reconstructed conversion radii ΔR in order to find the best combinations in cases where there were ambiguous associations. A constrained fit was then applied to the electron-positron pair candidate which forced a common conversion point with zero opening angle and collinearity between the momentum sum and the line from the beam spot to the conversion point.

2.4 Photon detection efficiency. Resolutions.

The photon detection efficiency, i.e. conversion probability combined with the reconstruction efficiency, was determined with the MC events and tabulated against three variables: E_γ, Θ_γ, (the photon polar angle to the beam) and θ_γ (the photon polar angle to the parent jet axis). The

efficiency varies with the energy from zero at 0.2 GeV up to 4%–6% at 1 GeV, depending on the two other variables. Typical dependences of the efficiency on E_γ and θ_γ are shown in Fig. 1a, b.

The accuracy of the converted photon energy measurement was found to be about $\pm 1.2\%$ in the given kinematic range. The angular precision of the photon direction reconstruction is presented by Fig. 1c, d, in which the distributions of the difference between the generated and reconstructed photon angles Θ_γ and Φ_γ are shown. These distributions have a Breit–Wigner shape, as expected for the superposition of many Gaussian distributions of varying width [58]. The full widths (Γ's) of the $\Delta\Theta_\gamma$ and $\Delta\Phi_\gamma$ distributions are 4 and 5 mrad, respectively.

The importance of good angular resolution in studying anomalous soft photons was shown in the hadronic beam experiment studies where most of the anomalous soft photons were observed inside a cone of 10–20 mrad around the beam direction [8, 11]. In those experiments the angular accuracy was determined by the precision of the measurement of the photon polar angle θ_γ, which varied between 1 to 6 mrad (while the accuracy of the beam direction measurement was about 0.1 mrad).

In hadronic decays of Z^0 bosons the accuracy of the measurement of the angle between the initial quark direction and the emitted photon is determined mainly by the angular accuracy of the reconstruction of the former, represented by the jet axis. Typical values of this accuracy in two-jet e^+e^- annihilation events were reported to be between 50 and 60 mrad [59], depending slightly on the jet-finding algorithm (with best results coming from the LUCLUS code). These results were tested with DELPHI MC events and a similar accuracy was found for the initial quark direction reconstruction. Namely, the mean deviation of the reconstructed jet axis from the primary quark direction for jets of momenta > 40 GeV/c was found to be about 40 mrad, as can be deduced from the distribution illustrated by Fig. 1e, and increases up to 50 mrad for smaller jet momenta. This is much worse than the corresponding accuracy of hadronic beam experiments. The accuracy does not improve by selecting "good events" with small missing energy and/or small missing longitudinal and transverse momenta. A rather moderate improvement of the accuracy (to 25–30 mrad) can be achieved by selecting two-jet events with the jet acollinearity smaller than 20 mrad, at the price of a loss of 80% of the two-jet event statistics. No such selections were implemented in this analysis.

Thus the available accuracy of the determination of the initial quark direction in this analysis is expected to spread the angular, p_T, and (most prominently) p_T^2 distributions of the possible anomalous soft photon signal as compared to the experiments with hadronic beams.

2.5 Selection cuts and data samples

Events involving the hadronic decays of the Z^0 from the DELPHI data of the 1992 to 1995 running periods were used in this analysis.

Selection of the hadronic events was based on large charged multiplicity ($N_{ch} \geq 5$) and high visible energy
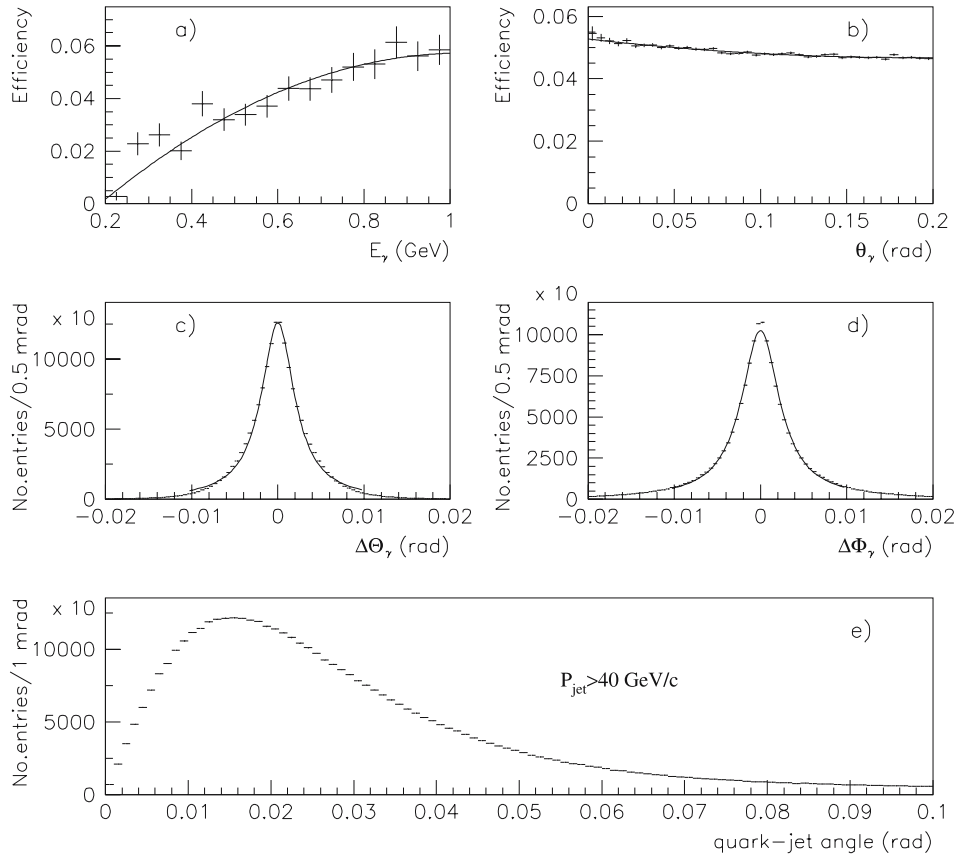

DELPHI

The *curves* in Fig. 1a, b are 2nd order polynomial fits used for the efficiency interpolation. The curves in Fig. 1c, d are the fits by Breit–Wigner form's (see text)

($E_{\mathrm{vis}} \geq 0.2 E_{\mathrm{cm}}$). In addition, the condition $30° \leq \Theta_{\mathrm{thrust}} \leq 150°$ was imposed, where Θ_{thrust} is the angle between the thrust axis and the beam direction. These criteria correspond to an efficiency of $(85.2 \pm 0.2)\%$ with a $Z^0 \to \tau^+\tau^-$ contamination of $(0.4 \pm 0.1)\%$.

A total of $3\,498\,655$ events of real data (RD) was selected under these cuts and confronted with 8×10^6 MC events selected under the same criteria and properly distributed over all the running periods.

Jets were reconstructed using the detected charged and neutral particles of the event, the charged particles being selected under the following criteria:

– $p > 400$ MeV/c;
– $\Delta p/p < 100\%$;
– $20° \leq \Theta \leq 160°$;
– track length > 30 cm;
– impact parameters below 4 and 10 cm in the $R\Phi$ and Z projections, respectively.

The neutral particles were taken within the geometrical acceptances of the subdetectors in which they were recon-

structed, within the selection criteria of the appropriate subdetector pattern recognition codes [45, 46], without additional cuts.

The selection of jets (whatever jet reconstruction algorithm, LUCLUS, DURHAM, or JADE having been used) was made with the following cuts:

– $30° \leq \Theta_{\mathrm{jet}} \leq 150°$;
– $P_{\mathrm{jet}} \geq 5$ GeV/c;
– no identified electrons (positrons) were allowed in the jets (electron identification with a standard DELPHI tag);
– if the jet charged multiplicity $N_{\mathrm{ch}} = 1$, the charged particle must be identified to be not an electron/positron (which is a stronger cut than the rejection of a particle identified as an electron/positron).

The selection of converted photons was made with the following cuts:

– only converted photons with both e^+, e^- arms reconstructed were considered;
– $20° \leq \Theta_\gamma \leq 160°$;

– $5\,\text{cm} \leq R_{\text{conv}} \leq 50\,\text{cm}$, where R_{conv} is the conversion radius;

– $200\,\text{M}eV \leq E_\gamma \leq 1\,\text{GeV}$.

A total of $682\,364$ converted photons was selected under these cuts in the RD and $1\,521\,030$ converted photons in the MC.

3 Systematic biases and their uncertainties

In view of the worsening of the signal detectability mentioned in Sect. 2.4, the quality of the MC data becomes important and a highly accurate simulation of the experimental conditions in the MC stream, i.e. minimization of systematic effects biasing the MC distributions with respect to the RD ones, is paramount. Systematic effects due to this bias in the MC data are classified into two types: "software" and "hardware" systematics.

The software systematics are related to an improper reproduction of experimental spectra of photons and charged particles by the MC event generator. The former affects directly the MC produced photon distributions, while the latter does this indirectly by biasing the reconstructed jet direction. Similar bias can be induced by a jet-finding algorithm. Estimates for systematic uncertainties of this type are given in Sect. 3.2.

The hardware systematics are related to biases in the simulation of experimental conditions in the MC stream, i.e. those which appear when transporting MC photons through the DELPHI setup and reconstructing them (after conversion in the DELPHI setup material) from hits simulated in the TPC. These features have been extensively studied throughout all the LEP1 period, with necessary corrections being introduced to the MC code. Some details of this study can be found in papers [47, 60]. However, in this analysis an additional procedure was implemented to improve the simulation of experimental conditions in the MC data, called "recalibration".

3.1 Reduction of hardware systematic bias

The idea was to use wide angle photons ($\theta_\gamma > 200\,\text{mrad}$), for which no signal of anomalous soft photons is expected, to re-normalize the material distribution along the photon path in the simulation, and to account for possible differences in reconstruction of converted photons from the TPC hits along e^+e^- tracks in the MC and RD. Two types of recalibration were applied. In the first one the wide angle soft photons from the MC and RD samples were collected into two-dimensional distributions, conversion radius R_{conv} versus the photon polar angle relative to the beam axis, Θ_γ. For the second type of recalibration the photons were binned according to E_γ. Bin widths of the calibration distributions were varied by factors up to 4 in order to check the stability of the procedure relative to the binning. The distributions, normalized to an equal number of jets passing the selection criteria, were used to obtain correction coefficients in appropriate bins of the above variables. The corrections were then applied to the MC data.

Both recalibration procedures were tried and have been found to give similar results for the photon rates integrated over the variables used, agreeing within the systematic errors discussed in the next paragraph (see also Sect. 6.4). The results were stable relative to the change of the jet-finding algorithm (LUCLUS, DURHAM or JADE codes). On the other hand, the calibration coefficients varied over LEP1 running periods due to changes in the DELPHI detector, i.e. changes of material distribution in front of the TPC, e.g. due to upgrade of the VD, etc., which required them to be found and used individually for each of the running periods.

To illustrate the quality of the data after recalibration, the distribution of the wide angle, $0.2 < E_\gamma < 1\,\text{GeV}$ photons against the photon polar angle with respect to the beam direction, Θ_γ, is displayed in Fig. 2. The part of the MC data statistically independent from those involved in the calculation of the recalibration coefficients is used for this, being properly distributed over the data-taking periods considered. The averaged integral difference between the MC and RD in this plot is below 0.9% (with an excess in MC). Expressed in the rate of photons having $p_T < 80\,\text{MeV/c}$ (the p_T range under study) which is $18.4 \times 10^{-3}\,\gamma/\text{jet}$, the difference is below $0.16 \times 10^{-3}\,\gamma/\text{jet}$. This value is used as an estimate of the systematic errors of hardware origin in the MC data. It is quoted in Table 1 together with other systematic error estimates considered below.

3.2 Estimation of software systematic errors

The largest contribution to the software systematic error was found to come from the uncertainty for deviations of the MC spectra produced with the event generator JETSET 7.3 PS, implemented to obtain the principal MC data sets used in this analysis, from the correct distributions of photons in the selected kinematic range, $0.2 < E_\gamma < 1\,\text{GeV}$, $p_T < 80\,\text{MeV/c}$. These deviations could happen either due to an improper description of the QCD processes in this kinematic range by the model used in the generator (string fragmentation model, [48]), or due to an inadequate representation of the full set of unstable hadrons decaying radiatively at the final stage of the hadronization mechanism.

The systematic errors due to the JETSET generator model and its tuning were estimated in two steps. First, the MC data were used with three different tunings described in [49, 50]. In particular, the invariant mass cutoff of parton showers Q_0, below which partons are not assumed to radiate gluons, and which is important in the soft kinematic region, was varied between 1.73 and 2.25 GeV/c^2 (other parameters correlated with this also being varied in order to keep the overall description of the data as good as possible)[2]. Comparing the photon spectra in our kinematic region for all the three tunings, it was found that the integral photon rates vary within ±0.4% which can be used as

---

[2] At generator level, the stability of the soft photon rate was tested in a wider range of the Q_0, from 0.3 to 2.25 GeV/c^2.
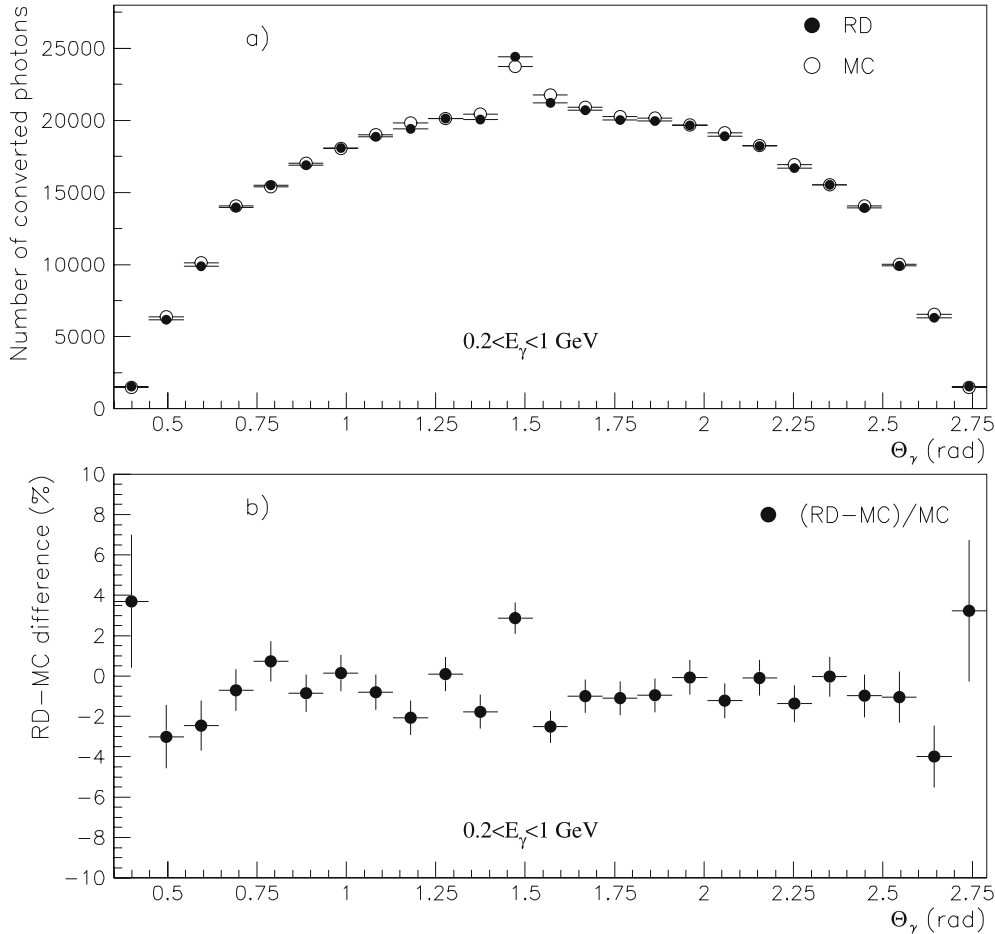

DELPHI

Fig. 2. a The RD and MC angular distributions (the polar angles relative to the beam direction, Θ_γ) for photons produced in hadronic decays of the Z^0 and converted in the DELPHI detector before the TPC. The photon kinematic range is $0.2 < E_\gamma < 1$ GeV and the photon polar angle relative to the parent jet direction $\theta_\gamma > 200$ mrad. The MC data were corrected by the recalibration procedure reducing the difference in material distributions in the RD and the MC and possible pattern recognition biases (see text); **b** the relative difference between the RD and corrected MC distributions

an estimate of the systematic error due to generator tuning. Expressed in photon rates, the difference is at the level of $0.08 \times 10^{-3} \gamma$/jet.

Then the MC data produced with other commonly used MC generators, ARIADNE and HERWIG were studied.

The description of a parton shower by ARIADNE is based on color dipoles [51, 61], and that of HERWIG on the coherent parton branching mechanism [52]. Unlike the results for high energy isolated photons reported in [37, 39, 44], no big difference between the JETSET and ARIADNE

Table 1. Systematic uncertainties of the background of hadronic decay photons in the range of photon $p_T < 80$ MeV/c for the data uncorrected for detection efficiency. The total systematic error is the quadratic sum of the individual errors

Total	0.27	23

[*)] The signal rate is defined in Sect. 5.1

generators was found in the kinematic range studied in this work. As will be shown below (Sect. 6.2), a systematic uncertainty due to the generator model for the rate of soft photons of $p_T < 80$ MeV/c can be estimated to be at the level of 0.18×10^{-3} γ/jet. Combining this value with the uncertainty due to the tuning, the systematic error due to the event generator was estimated to be 0.20×10^{-3} γ/jet. This value is quoted in Table 1.

A sensitive cross-check of the generator model systematics, making use of charged particle spectra (see Sect. 6.5), has shown that the possible systematic bias of this type is likely to be much less than the quoted errors. Another cross-check, based on the comparison of the π^0 production in the MC and RD (see Sect. 6.6) involving both the generator and hardware systematics, also demonstrated results in a good agreement with the estimations above. The cross-checks indicate some overestimation of the systematic errors due to the generator model quoted above, nevertheless they are retained.

The next systematic effect to be considered may originate from the possible inadequate representation of unstable hadrons decaying radiatively (other than π^0's) in the MC code, biasing the MC hadron outcome as compared to the RD. Its study is described in detail in Sect. 6.7. It follows from this study that the value of a systematic error due to effects of this type is at the level of 0.05×10^{-3} γ/jet.

In order to determine the scale of a possible variation of results due to an implementation of a jet-finding algorithm other than LUCLUS, the DURHAM and JADE algorithms were also used in the analysis (see Sect. 5.1). From the variations obtained the systematic error due to the jet finder was derived to be at the level of 0.07×10^{-3} γ/jet.

Since the results of this work are presented both uncorrected and corrected for the detection efficiency, in the latter case the systematic errors resulting from the correction have to be taken into account. The integral systematic error due to the efficiency correction in the photon p_T range below 80 MeV/c was found to be 6% of the corrected photon rates (both, for the RD and for the MC, as well as for their difference). This error has two components. The first one is an inaccuracy of the efficiency determination within the method implemented for this procedure (see Sect. 2.4), and is equal to 4%. It was calculated from the MC data by comparing the photon p_T distribution taken at the output of the event generator to the analogous distribution of reconstructed photons corrected for efficiency, the former being taken with the same cuts as the latter. The second component of the error above is related to the choice of the variables used to construct the efficiency tables. For example, the photon opening angle to the closest track can be used instead of the photon polar angle to the parent jet, θ_γ. Another choice of an efficiency table variable could be the momentum of the closest track, or the jet charged multiplicity N_{ch} (note, all these variables make the efficiency sensitive to the track density near the jet axis). These possibilities were tried and indicate the uncertainty of this type in the efficiency finding to be about 5%.

In a similar way the appropriate systematic errors due to corrections for efficiency in individual bins of the photon p_T distribution were found.

4 Calculation of the inner bremsstrahlung

The principal sources of direct soft photons from the reaction (1) are expected to be bremsstrahlung from colliding $e^+ e^-$ (initial state radiation) and inner bremsstrahlung from final hadronic states. For soft photons both source rates can be calculated at once using either of two universal formulae:

i) the formula, derivable from the Low paper [2] (see also [16, 62]), explicitly displayed for the first time in [4] and then used by others [5–8, 11]:

$$\frac{dN_\gamma}{d^3\mathbf{k}} = \frac{\alpha}{(2\pi)^2} \frac{1}{E_\gamma} \int d^3\mathbf{p}_1 \ldots d^3\mathbf{p}_N \sum_{i,j} \eta_i \eta_j$$
$$\times \frac{-(P_i P_j)}{(P_i K)(P_j K)} \frac{dN_{hadrons}}{d^3\mathbf{p}_1 \ldots d^3\mathbf{p}_N}, \qquad (2)$$

where K and $\mathbf{k}$ denote photon four- and three-momenta, P are four-momenta of beam e^+, e^- and of the N charged outgoing hadrons, and $\mathbf{p}$ are three-momenta of the latter; $\eta = 1$ for the beam electron and for positive outgoing hadrons, $\eta = -1$ for the beam positron and negative outgoing hadrons, and the sum is extended over all the $N + 2$ charged particles involved; the last factor in the integrand is a differential hadron production rate;

ii) the Haissinski formula [63, 64], which was tested to be more stable with respect to lost (undetected) particles and was used in [7, 8, 11]. It has the same form as (2) with the scalar products of four-vectors $-(P_i P_j)$ being replaced by $(\mathbf{p}_{i\perp} \mathbf{p}_{j\perp})$, where $\mathbf{p}_{i\perp} = \mathbf{p}_i - (\mathbf{n}\mathbf{p}_i)\mathbf{n}$ and $\mathbf{n}$ is the photon unit vector.

It is known (see [8, 11]), that the two formulae give results in complete agreement when used with MC generated particles unaffected by detector response, i.e. when all charged particles of an event enter into the formulae, with their precise momenta. We have tested the validity of this feature for our case in the following way. For every reconstructed jet the parameters of the generated charged particles lying in the forward hemisphere of the jet (including the corresponding beam particle) were collected and bremsstrahlung distributions for them were calculated, with the polar angle of the bremsstrahlung photon to the reconstructed jet direction being an angular variable. Note that this method, i.e. usage of *generated* particle momenta while projecting the produced photon onto the *reconstructed* jet direction, is both a) precise and b) automatically accounts for the angular resolution of the jet direction. Both formulae gave the same predictions, and these results were used in our estimates for the expected bremsstrahlung rates. Integrated over our kinematic range, the total bremsstrahlung rate was obtained to be 17.1×10^{-3} γ/jet; after convolution with the detection efficiency, it drops to the value of 0.340×10^{-3} γ/jet. Note that the contribution of the ISR to these rates is small, being at the level of about 1.5% of them. The smallness is easy to explain: although the ISR from electron/positron beams is much more intense than the ISR from hadron

Table 2. Systematic uncertainties of the inner hadronic bremsstrahlung calculations in the range of photon $p_T < 80$ MeV/c. The total systematic error is the quadratic sum of the individual errors. The uncertainties, given in absolute photon rates (2nd column of the table) correspond to the case of the data uncorrected for detection efficiency

Source	Value, 10^{-3} γ/jet	Percentage of brems rate
Formula (2)	0.014	4
Event generator	0.017	5
Jet finder	0.010	3
Convolution with efficiency[*]	0.029	9
Total	0.038	11

[*] The systematic error due to convolution with efficiency has to be taken into account when dealing with the results uncorrected for efficiency only.

beams in experiments [5–8, 11], where it contributed a significant amount to the detected photon rate, all the extra photons in this experiment are emitted at very small polar angles with respect to the beam direction, with the angular distribution peaking at $\Theta_\gamma = \sqrt{3}/\Gamma$, where Γ is a beam Lorentz factor ($\Gamma = 0.89 \times 10^5$ at the Z^0 peak), thus yielding few photons in the barrel region.

The yield of the final state radiation from quarks of Z^0 disintegrations is similarly small. For its estimate the photon implementation in JETSET [54] was used. The Q_0 scale introduced for the QED part of the shower was varied[3] down to its natural lower limit, the constituent quark mass, which is 300 MeV/c^2. The production rate of photons off quarks in our kinematic range was found to be at the level of 3% of the hadronic bremsstrahlung rate[4]. In what follows, neither this nor the ISR yields will be discussed further; they are reduced in the RD−MC difference and will be ignored.

It follows from [3] that the applicability of the formulae above to the soft bremsstrahlung calculation is restricted in our case (e^+e^- annihilation into hadronic jets at $\sqrt{s} = M_Z$) to the photon kinematic domain $p_T \ll m_\pi c$, which is a stronger condition than the one mentioned in the introduction for hadronic reactions. However, it has been verified (see next paragraph) that the applicability holds even at that weaker condition, with an accuracy of about 10%. Nevertheless, the stronger condition is also typically satisfied in our case since the p_T distribution of calculated inner hadronic bremsstrahlung with photons projected onto the plane perpendicular to the initial quark direction (i.e. before the spread induced by the angular resolutions) was found to peak at 30 MeV/c.

To test the applicability of the formula above the predictions for the initial state radiation calculated with this formula were compared with those of the DYMU3 generator [53]. For $0.2 < E_\gamma < 1$ GeV bremsstrahlung photons

produced within 100 mrad angles to the *beam* direction (P_T to the *beam* below 100 MeV/c) the results coincided within 4%. For the photons produced within 100 mrad angles to a *jet* direction (the average P_T to the *beam* is 400 MeV/c) the difference reached 11%. Since the range of the photon p_T under study in this work is restricted to be within 80 MeV/c, the estimate for the systematic error in the bremsstrahlung calculations due to formula (2) appears to be below 4% of the calculated bremsstrahlung rate. This error, together with further contributions to the bremsstrahlung calculation uncertainty described below, is given in Table 2.

The stability of these calculations was tested using different event generators (JETSET, ARIADNE and HERWIG) and different jet finders (LUCLUS, DURHAM, JADE) obtaining bremsstrahlung rates agreeing within 5% when changing the generator (with LUCLUS as jet finder) and 3% when changing the jet finder (with JETSET as an event generator), see Table 2.

Finally, when dealing with the results uncorrected for the detection efficiency, the generated bremsstrahlung distributions have to be convoluted with the efficiency. This induces an additional systematic error of 9% to the bremsstrahlung predictions due to the uncertainty in the efficiency determination. This error has two components, similar to those discussed at the end of Sect. 3.2. The first one is an inaccuracy of the efficiencies within a given determination procedure (Sect. 2.4), and is equal to 7%. It was calculated from the MC data by comparing the photon p_T distribution, taken at the output of the event generator and convoluted with the detection efficiency, on the one hand, to the analogous distribution of reconstructed photons (i.e. at the output of the MC stream), on the other hand. The other component of the error above is related to the choice of efficiency table variables and is equal to 5% of the calculated bremsstrahlung rate.

5 Experimental results

5.1 Photon distributions. Signal extraction

The results obtained in this study are presented both uncorrected and corrected for the photon detection efficiency.

---

[3] Together with these variations the QCD Q_0 scale was varied within the range of 0.3 to 2.25 GeV/c^2, showing a weak influence of this cutoff on the production rate of soft photons off quarks.

[4] The situation changes little when decreasing the QED Q_0 cutoff down to the extreme limit for it, which is about 4 MeV/c^2, due to a weak (logarithmic) dependence of the quark bremsstrahlung rate on the Q_0.
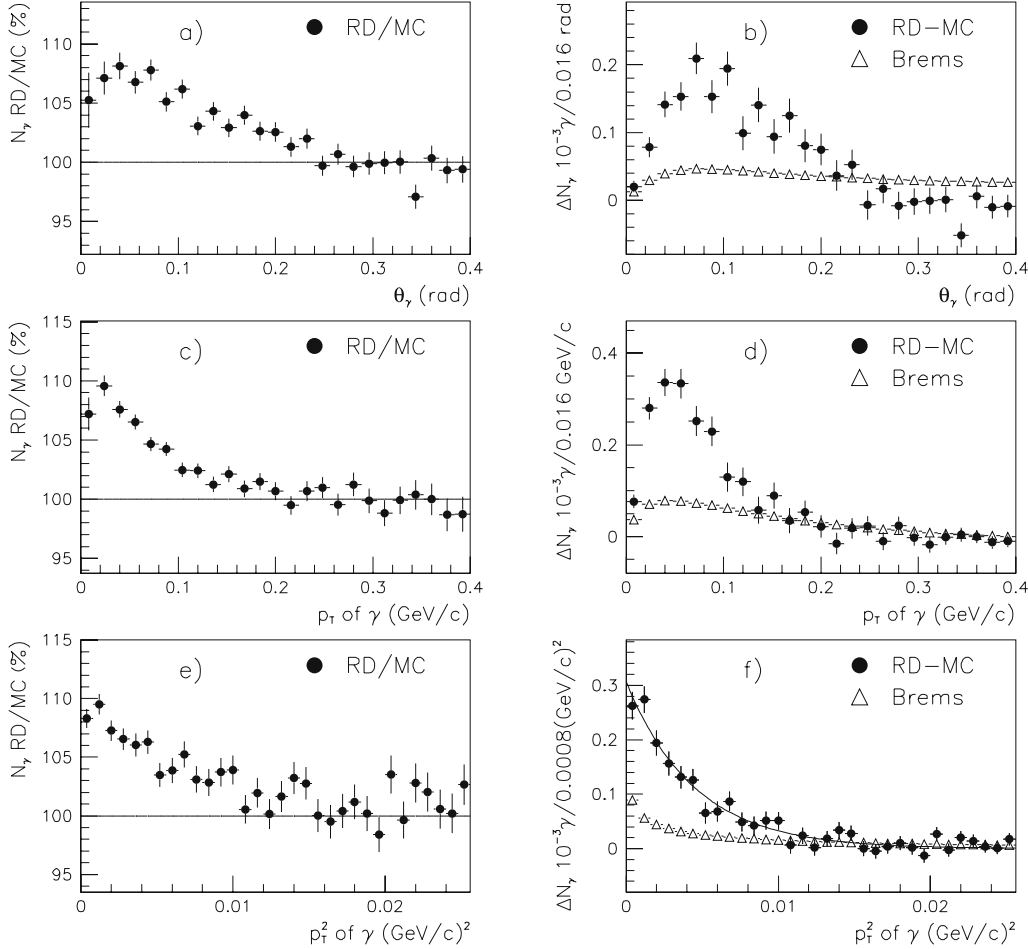

DELPHI

Fig. 3. Experimental spectra obtained with the general selection. *Left panels*: the ratio of the RD and MC distributions for **a** θ_γ (photon polar angle relative to the parent jet direction); **c** photon p_T; **e** photon p_T^2. *Right panels*, **b**, **d**, **f**: the difference between the RD and MC distributions for the same variables, respectively. "Brems" corresponds to the inner hadronic bremsstrahlung predictions. The errors are statistical. The *curve* in Fig. 3f is the fit by an exponential (see text)

However, the principal set of results is given *uncorrected* for the efficiency. This is motivated by the fact that applying efficiency corrections increases both the statistical and systematic errors of the results. The latter occurs due to an uncertainty in the efficiency determination. The former happens because the entries with the smallest efficiency, i.e. with the largest weights, dominate the distributions. For example, with the efficiency corrections applied, the softest photons enter the distributions with weight factors up to one order of magnitude higher than those for the photons of moderate energy. Since this article is aimed mainly at the demonstration of the existence of excess photons, its principal results have to be presented with the highest possible statistical and systematic accuracy. Therefore, efficiency-corrected results will be given only when the absolute photon rates are discussed, namely in Sect. 5.2.

Thus we start with the θ_γ, p_T and p_T^2 photon distributions uncorrected for efficiency. The RD and MC distributions are presented in Fig. 3 divided by and subtracted from each other. The RD$-$MC distributions (the right column of panels in Fig. 3) are given in units of 10^{-3} γ/jet, and are accompanied by calculated bremsstrahlung rates. All the distributions shown demonstrate an excess of soft

photons in the RD as compared to the MC, and this excess is apparently higher than the expected bremsstrahlung level[5].

To quantify the excess the difference between the RD and MC was integrated in the p_T interval from 0 to $80\,\mathrm{MeV/c}$ ($p_T^2 < 0.64 \times 10^{-2}\,(\mathrm{GeV/c})^2$), and the value obtained was defined as a signal. The excess of the RD over the MC as a function of p_T^2 was fitted by an exponential. The results obtained are:

---

[5] There is a systematic excess of the bremsstrahlung predictions over the data at the angles $\theta_\gamma > 200$ mrad. It comes from our recalibration procedure which assumed that no physical excess of photons exists at these angles. This assumption, invalid in principle since there exists a certain hadronic bremsstrahlung radiation at wide angles, induces a small systematic bias to the whole angular range due to an overcorrection and consequently lowers the observed photon excess rate. However, for the sake of clarity of the presentation we neglect this bias. Left neglected, it decreases the signal by an insignificant amount, while its accurate treatment would require including the bremsstrahlung calculation at wide angles into the procedure of the recalibration which we preferred to avoid here.

– signal rate

$$R_{\mathrm{RD-MC}} = (1.17 \pm 0.06 \pm 0.27) \times 10^{-3}\,\gamma/\text{jet} \qquad (3)$$

while the expected level of the hadronic photon background in this range taken from the MC is

$$R_{\mathrm{MC}} = (18.40 \pm 0.04 \pm 0.26) \times 10^{-3}\,\gamma/\text{jet}. \qquad (4)$$

The calculated level of the inner hadronic bremsstrahlung in the same range is, according to Sect. 4,

$$R_{\mathrm{brems}} = (0.340 \pm 0.001 \pm 0.038) \times 10^{-3}\,\gamma/\text{jet}. \qquad (5)$$

Evaluated in terms of the inner bremsstrahlung rate, the signal is $3.4 \pm 0.2 \pm 0.8$. The rates (3) and (5) together with the other ones, obtained under various conditions described below, are given in Table 3.

– the slope of the excess p_T^2 distribution (assuming $\mathrm{d}N_\gamma/\mathrm{d}p_T^2 \sim exp(-Bp_T^2)$ for the excess photons) is fitted to the value of $B = (251 \pm 21)(\mathrm{GeV}/c)^{-2}$, which is also a good estimation for the slope of the inner hadronic bremsstrahlung, but is an order of magnitude steeper than the typical slopes of p_T^2 distributions of photons in hadronic Z^0 decays.

As can be seen from (3) and (5), the relative strength of the signal observed (i.e. signal strength expressed in terms of the bremsstrahlung rate) is comparable to the amplitudes of the anomalous soft photon effects seen in the hadronic beam experiments [5–8, 11].

In order to check the independence of the signal amplitude on the jet-finding algorithm the DURHAM and JADE algorithms were applied to form jets instead of LUCLUS. The results were found to agree within the statistical errors, i.e. they are stable against the change of the jet-finding algorithm, see Table 3. The LUCLUS to the DURHAM general selection signal ratio was found to be 1.10 ± 0.07 and the LUCLUS to the JADE ratio was 1.09 ± 0.07.

5.2 Data corrected for efficiency

The θ_γ, p_T and p_T^2 photon distributions for the data corrected for the efficiency are given in the same form as those for the uncorrected ones and are displayed in Fig. 4. The integral signal rate (the RD to MC rate difference integrated over the p_T range from 0 to 80 MeV/c) is $(69.1 \pm 4.5 \pm 15.7) \times 10^{-3}\,\gamma/\text{jet}$ and is given in the last line of Table 3. It is about 7% of the total jet rate, i.e. the absolute strength of the signal (the probability to have an excess photon per jet) is also similar to that found in the hadronic beam experiments[6]. The corresponding inner hadronic bremsstrahlung rate is $(17.10 \pm 0.01 \pm 1.21) \times 10^{-3}\,\gamma/\text{jet}$.

The differential signal rates $(\mathrm{d}N_\gamma/\mathrm{d}p_T$ per 1000 jets) corrected for efficiency are presented in $10\,p_T$ bins in Table 4, together with the corresponding predictions for the inner hadronic bremsstrahlung.

5.3 Zero signal experiment

In order to verify the analysis procedure it was applied to the photon kinematic domain where the anomalous soft photon excess was highly improbable (the zero experiment). Such a domain was defined as follows.

Instead of defining the photon kinematic variables with respect to the parent jet direction, the direction opposite to that of the most distant jet was chosen, while the acollinearity between this and the parent jet was required to be greater than 200 mrad. Thus, the procedure separates photons within the jets having an acollinear opposite jet and projects them onto the plane perpendicular to the direction of the latter. All other elements of the analysis were kept untouched, including the calculation of the bremsstrahlung predictions.

---

[6] Here a correspondence of the photon production in a jet (this study) to its production in a minimum bias interaction event of the hadronic beam experiments is assumed.

Table 3. Signal amplitudes in units of $10^{-3}\gamma$ per jet, obtained under various selection criteria. The jets satisfy all the selection cuts described in Sect. 2.5 and additional cuts (if any), as indicated in this table. The jets were formed by the LUCLUS jet-finding code unless the DURHAM or JADE codes are referred to explicitly. The errors are statistical only. Information on the systematic errors of the experimental photon rates and the bremsstrahlung predictions is given in Table 1 and Table 2, respectively

|	Selection conditions	Signal	Brems
1	General selection	1.170 ± 0.062	0.340 ± 0.001
2	General selection, DURHAM	1.060 ± 0.067	0.351 ± 0.001
3	General selection, JADE	1.070 ± 0.074	0.332 ± 0.001

	General selection, signal corrected for efficiency	69.1 ± 4.5	17.10 ± 0.01

DELPHI
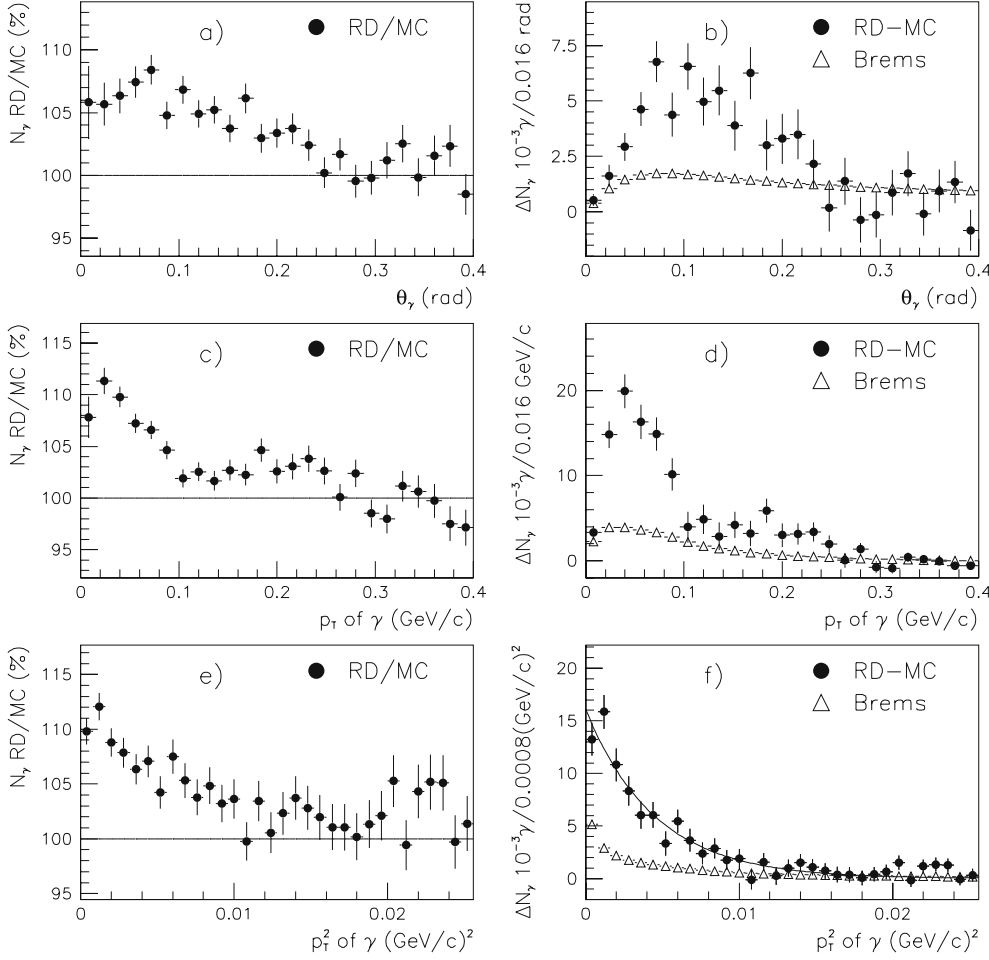

Fig. 4. The same as in Fig. 3, corrected for the efficiency of photon detection

The photon distributions obtained with this procedure are shown in Fig. 5 for the RD, for the MC, and for their difference. The latter distributions agree well with the bremsstrahlung predictions, though due to the relatively high statistical errors they are also compatible with zero in the range of $p_T < 80$ MeV/c. The corresponding photon rates are given in Table 3.

The results of the zero experiment have two different applications. First, they show that no anomalous photons are produced at the very beginning of the frag-

Table 4. Differential signal and inner hadronic bremsstrahlung rates as a function of the photon p_T, in units of 10^{-3} γ/jet integrated over the p_T bin of 8 MeV/c width. The first errors are statistical, the second ones are systematic

The errors are statistical

mentation process, before the first hard gluon emission. Had the photon radiation been produced at this stage (when two initial quarks are still highly collinear) the signal would be observed when relating the photon with the "antipode" of its parent jet, because the antipode jet would memorize the initial direction of the parent quark (which emits the photon in this scenario), unless a hard gluon emission deviates the antipode quark also.

The other use of the zero experiment is a confirmation of a good suppression of definite systematic effects, relevant also to our kinematic region and capable of producing a spurious excess. These effects are mainly of hardware systematics: an underestimation of material amount in front of the TPC in the MC code; a global difference in the reconstruction of the converted photons in the RD and MC; an improper treatment of background hits (noise, cosmics, etc.) in the RD by the pattern recognition program.

A quantitative estimation of possible biases induced by these effects has been given in Sect. 3.1. Additional tests for these and other systematic effects are described in the following section.

6 Study of systematic biases capable of imitating the observed excess

6.1 Test for external bremsstrahlung

The most straightforward background capable of imitating the anomalous photon signal is the so called external bremsstrahlung, which is the bremsstrahlung from electrons (positrons) produced either in (semi)leptonic decays of hadrons or by internal or external conversion of photons from hadronic decays, when these electrons pass through the experimental setup. It also tends to peak at small p_T^2, and if it is underestimated by the MC, this could lead to an apparent excess of soft photons in the RD events. The rejection of jets containing at least one electron applied throughout this analysis (see Sect. 2.5) was implemented in order to suppress this effect. However, electrons within the jets which escaped identification could be, in principle, responsible for the excess observed.

To check this hypothesis, the level of electron admixture in jets was varied from its natural ratio (dropping the rejection of jets containing identified electrons) to a 5 times smaller one, by applying a loose tag for the elec-

tron identification[7]. Thus, if an essential part of the signal comes from the electron bremsstrahlung, the signal rate should increase by several times when passing from the maximal rejection case (with loose electron tag) to the case with no rejection at all.

In fact, no enhancement of the signal rate was found when dropping the rejection of jets containing identified electrons (see Table 3, lines 5, 6), while the RD and MC rates both changed, by factors of 1.0944 ± 0.0055 and 1.0940 ± 0.0038, respectively (the quoted numbers and their statistical errors are obtained with photons in the $p_T < 80\,\mathrm{MeV/c}$ range). Furthermore, the maximal electron rejection (with the loose tag, Table 3, lines 7, 8) does not decrease the signal, which should occur in the case of a contribution to the latter due to the external e^+e^- bremsstrahlung (the RD and MC rates decreased by factors of 0.9386 ± 0.0049 and 0.9400 ± 0.0034, respectively).

---

[7] The electron identification in DELPHI has different levels of electron tagging. Normally we used the standard tag, which provides electron identification with efficiency 55% for electrons having momenta above 2 GeV/c [46]. The loose tag has a higher electron identification efficiency, approaching 80%.

Thus the hypothesis of an extra amount of the external bremsstrahlung from electrons inside the jets in the real data as a source of the excess appears to be excluded.

6.2 Changing MC generator

In order to check that the observed excess is not an artefact originating from a particular feature of the implemented MC generator (JETSET), the photon spectra produced with it were compared to those from ARIADNE. They are plotted in Fig. 6. As can be seen from this figure, there is a rather weak prevalence of JETSET over ARIADNE at p_T below 80 MeV/c. This means that with ARIADNE as an event generator the excess of photons would be slightly increased. In amplitude, the observed difference is $0.18 \times 10^{-3}\,\gamma/\mathrm{jet}$. Being expressed in the units of the signal strength, it is less than 15% in the photon p_T range below 80 MeV/c. This value is used as an estimate for the systematic error due to the event generator (Sect. 3.2).

The comparison of JETSET with HERWIG shows a similar feature, with HERWIG data tending to decrease further the soft photon rate as compared to ARIADNE.
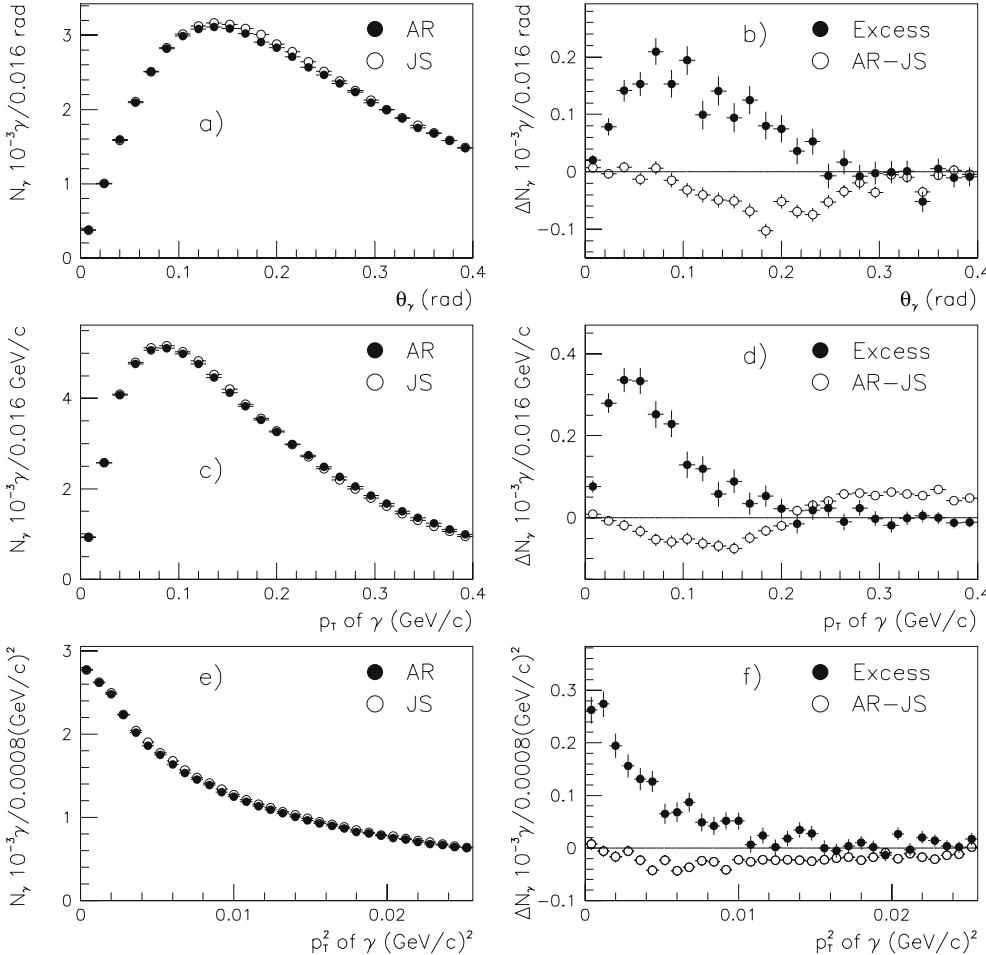

DELPHI

Fig. 6. Comparison of the JETSET (JS) and ARIADNE (AR) generators. *Left panels*, **a**, **c**, **e**: the MC θ_γ, p_T and p_T^2 distributions of photons as produced by JETSET and by ARIADNE. *Right panels*, **b**, **d**, **f**: the difference between the two MC distributions for the same variables (*open circles*). The RD−MC distributions from Fig. 3 presenting the observed excess are also displayed for comparison. The errors are statistical

Thus JETSET appears to be the generator giving the maximal soft photon yield among the tested event generators.

6.3 Secondary photons

When a high energy photon generates an e^+e^- pair in the material in front of the TPC the pair particles may radiate bremsstrahlung photons, which can enter our kinematic region. In most cases such photons have a small opening angle relative to the parent photon, which leads to a small-angle enhancement in the distribution of the two-photon opening angles. Such enhancements, at angles below 30 mrad, were seen in both the RD and MC distributions of the angles between two converted photons, but they cancelled in the RD/MC and RD−MC distributions. It follows from this that the given process is well reproduced in the MC stream and cannot be a source of the observed excess.

6.4 Comment on the pattern recognition bias

An important stage of the reconstruction of the converted photons is the reconstruction of their constituent e^+ and e^- tracks from hits left by them in the TPC. A possible different treatment of the hits in the MC and RD by the pattern recognition would induce a systematic bias to the photon reconstruction efficiency. This difference may come from numerous sources. Two of them are listed below:

– in the case of the real data the TPC can be loaded by external tracks, noise, cosmics, etc., which is difficult to reproduce in the MC stream, thus resulting in different TPC patterns being fed into the reconstruction program of the RD and MC;
– a difference in the production of true hits from the e^+ and e^- tracks of the photon conversion in the RD and the MC data may be induced by an improper setting of the TPC efficiency in the MC stream (e.g. simply due to TPC ageing), and may depend on the position of the photon conversion, e^+e^- track lengths (which vary with the photon energy) and even on the jet charged multiplicity, which produces a varying environment around the e^+e^- track hits.

This difference is expected to be reduced to a great extent by the recalibration procedure described in Sect. 3.1. The only possible pattern recognition distinction between the RD and MC whose compensation is not ensured by this

procedure can take place within the range of photon polar angles to the parent jet $\theta_\gamma \leq 200$ mrad, since the wide angle photons ($\theta_\gamma > 200$ mrad) were used for the recalibration. In this region the environment around the e^+e^- track hits may be affected by charged particles of the jet. In such a case the difference in the pattern recognition results should depend on the jet charged multiplicity. In order to test this possibility the RD to MC ratio was studied in several bands of the jet charged multiplicity, in three angular ranges: $\theta_\gamma < 100$ mrad, $100 \leq \theta_\gamma < 200$ mrad, and $200 \leq \theta_\gamma < 400$ mrad. The ratios obtained for the different N_{ch} bands are in mutual agreement (within individual angular ranges) and agree well with the analogous global ratios of the RD to MC (Table 5). This means that the pattern recognition results appear to be the same for the RD and MC within the full angular range under consideration.

6.5 Test with charged particles

The analysis of photon distributions described in Sect. 5.1 was applied to artificial photons produced from charged pions. The aim of this test was to check that the hadronization procedure of the MC event generator in the soft kinematic region has no big systematic bias as compared to the analogous process in the real data. Being directly implemented for charged particles (which are charged pions mainly), it has a straightforward relation to the π^0 production also due to the almost precise $SU(2)$ symmetry of the strong interactions[8] (earlier the idea of similar tests has been implemented in [4, 5]). Thus, the method was to take three-momenta of charged particles in the real and MC data as a starting point to represent π^0 distributions, to decay these "π^0's" into two photons, to convolute the resulting photon momenta with the photon detection efficiency and feed them into the analysis code.

The resulting distributions are shown in Fig. 7. They are similar to the genuine photon spectra (cf. Fig. 6), however the main result of this test is an excellent agreement between the RD and MC samples. The "signal" strength calculated in the same way as that for true photons is $(0.102 \pm 0.014) \times 10^{-3} \gamma$/jet, i.e. at the level of 9% of the photon signal (3). Therefore the hadronization mechanism of the applied MC code is concluded to work well as far

---

[8] There are processes which break the $SU(2)$ symmetry (e.g. decays of η, η'), but their contribution to the soft photon rate is small, see Sect. 6.7.

Table 5. RD to MC ratios in three ranges of θ_γ as a function of the jet charged multiplicity N_{ch}

| N_{ch} band	$\theta_\gamma < 100$ mrad	100 mrad $\leq \theta_\gamma < 200$ mrad	200 mrad $\leq \theta_\gamma < 400$ mrad
$1 \leq N_{ch} \leq 3$	1.060 ± 0.013	1.046 ± 0.010	0.980 ± 0.009
$3 < N_{ch} \leq 5$	1.074 ± 0.010	1.025 ± 0.007	1.001 ± 0.006
$5 < N_{ch} \leq 7$	1.049 ± 0.009	1.044 ± 0.007	0.973 ± 0.006
$N_{ch} > 7$	1.067 ± 0.007	1.028 ± 0.006	1.005 ± 0.005
all N_{ch}	1.064 ± 0.005	1.033 ± 0.004	0.994 ± 0.003

DELPHI

Fig. 7. Comparison of the RD and MC distributions of "photons" produced from charged particles (see text, Sect. 6.5). The RD−MC distributions for these "photons" are shown by *open circles*. The observed excess distributions (RD−MC from Fig. 3) are also displayed for comparison. The errors are statistical

as concerns the charged pion production. Being related via $SU(2)$ symmetry with the production of neutral pions, it is expected to reproduce it sufficiently well too. The direct comparison of π^0 production in the RD and MC is done in the next section.

6.6 π^0 tests

A general and powerful check of the adequacy of the MC data can be done via a comparison of the MC and RD $\gamma\gamma$ mass spectra, by comparing the π^0 signals detected in each data set. Note that the applicability of the results obtained with the π^0 tests holds for almost the whole soft photon sample under study since the photon production in the data is dominated by π^0 decays, which yield (according to the MC) almost 92% of photons in our kinematic range.

The production of π^0's in the DELPHI data of Z^0 hadronic decays was studied in [47] including the π^0's arising from two converted photons. The experimental result for such π^0's shows a tendency for an overestimation of π^0 production by JETSET 7.3 at low π^0 momenta ($< 1\,\mathrm{GeV}/c$). However the results of that work cannot be used

directly to estimate the systematic errors of the photon background rate in our kinematic range. Therefore a special analysis of π^0 production was done in this work to get such an estimation from π^0 signals extracted from the $\gamma\gamma$ mass distributions of converted photons.

The photons (at least two converted photons per jet were required) were subdivided into two energy bands: one band of low energy (LE) 0.2–1 GeV, and one band of higher energy (HE) 1–10 GeV. Each HE photon was combined either with a LE photon of a given jet or with a HE photon. Both photons in the combination were weighted by the recalibration corrections. The $\gamma\gamma$ mass distributions obtained are shown in Fig. 8 for both, the MC and the RD. It can be seen from these distributions that there are distortions of the lower-mass parts of the π^0 peaks. They are induced by the external bremsstrahlung radiation from at least one of the e^+e^- arms of a converted photon of the π^0. Therefore the spectra were fitted by two Gaussians superimposed over a smooth background, the second Gaussian being introduced to describe the distortions. The fit results have shown a small difference in the MC and RD widths of the first Gaussian, $(4.0 \pm 0.1)\,\mathrm{MeV}/c^2$ versus $(4.4 \pm 0.1)\,\mathrm{MeV}/c^2$, respectively,
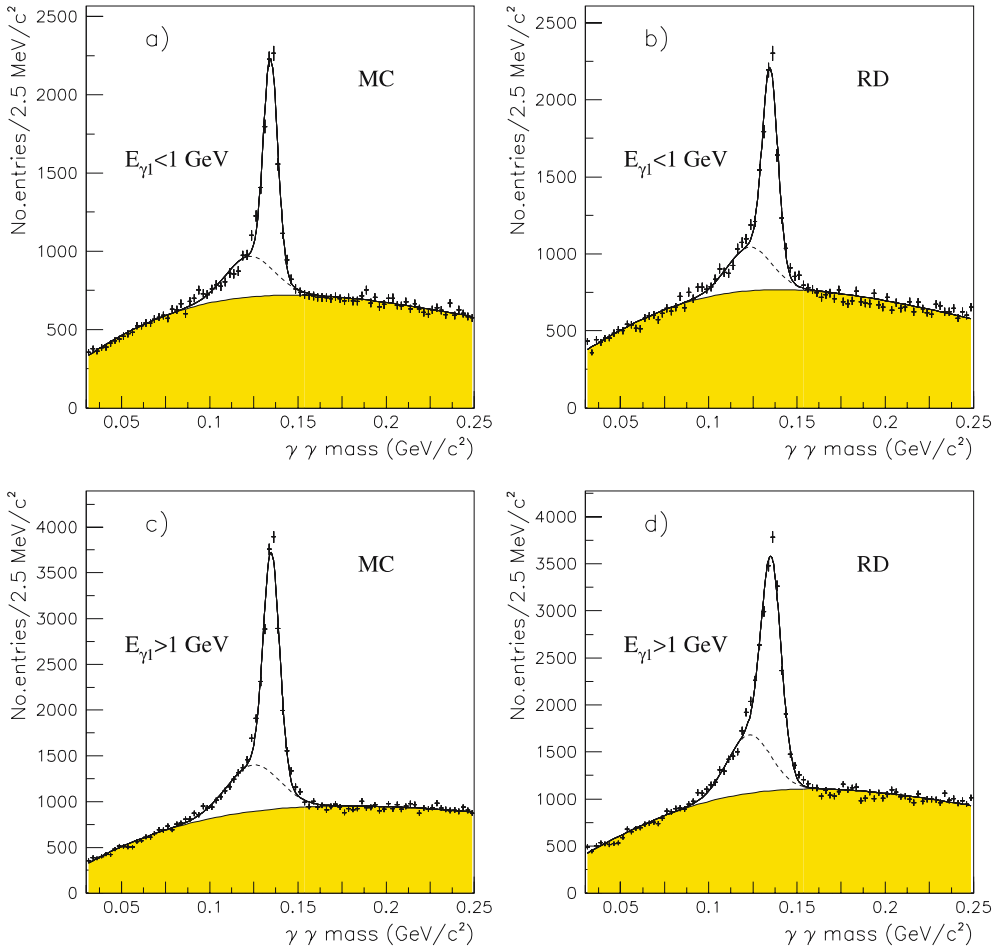

DELPHI

Fig. 8. Comparison of the MC and RD $\gamma\gamma$ mass distributions for the two converted photon combinations. **a**, **b** LE×HE combination; **c**, **d** HE×HE combination. The *dashed line* represents the distortion Gaussian (see text). The errors are statistical. The results of the comparison are given in Table 6

for LE×HE combinations, and $(4.8 \pm 0.1)\,\mathrm{MeV/c^2}$ versus $(5.6 \pm 0.1)\,\mathrm{MeV/c^2}$ for HE×HE combinations. The π^0 peak position was stable at $135\,\mathrm{MeV/c^2}$, as well as the 2nd Gaussian parameters, the widths of the latter being 13 and $15\,\mathrm{MeV/c^2}$ for the LE×HE and HE×HE combinations, respectively. The ratio of the integrals under the two Gaussians (with the background subtracted) was found to be about two in both cases. The sum of the integrals under the Gaussians represents the number of π^0's in an appropriate $\gamma\gamma$ mass distribution. They are given [9] in Table 6.

From the HE×HE results the HE photon RD to MC ratio was found to be 1.020 ± 0.007, i.e. the recalibration procedure succeeded in reducing the RD and MC difference to the level of 2% for these photons. For the LE photons the effect of the recalibration seems to be slightly better, the RD to MC ratio deduced from the LE×HE results is 0.986 ± 0.023 taking into account the factor 1.020 of the HE photon ratio obtained above. This agrees well with the re-

calibration results for the difference residuals discussed in Sect. 3.1 and illustrated by Fig. 2.

Thus the upper limit for the systematic bias of soft photon RD to MC ratio which can be obtained from the π^0 test with converted photons is 1.024 at the 95% C.L. In order to get an independent check of this result the whole procedure described above was repeated replacing the HE converted photon with a calorimetric (HPC) photon in the same energy band and within a Θ_γ range of $50° - 130°$. The HPC photons were combined with LE and HE converted photons being weighted by the second type of the recalibration procedure, i.e. with the energy binning. In spite of a worse mass resolution (by a factor of 4), the statistical gain due to combination of converted photons with those from the HPC was expected to give a statistical accuracy of the fit results comparable to those obtained with two converted photon analysis. Since the HPC photons may have their own systematic bias, the HPC×HPC combinations were also involved in the analysis.

The $\gamma\gamma$ mass distributions for these photon combinations are displayed in Fig. 9. No distortion effects are visible in the distributions due to the worse mass resolution and due to a smaller yield of the converted photons to the

---

[9] We do not give the individual Gaussian yields since they interfere strongly due to pile-up of the Gaussians, while their sum is close to being fit invariant.

Table 6. π^0 signal amplitudes (numbers of π^0's in the π^0 peaks) obtained with two combinations of converted photons and the upper limits for the RD/MC ratio of the converted LE photons extracted from the signals

	$LE_{conv} \times HE_{conv}$	$HE_{conv} \times HE_{conv}$
RD	9052 ± 147	19529 ± 206
MC	8999 ± 133	18774 ± 154
RD/MC	1.006 ± 0.022	1.040 ± 0.013
Resulting RD/MC for the LE photons: 0.986 ± 0.023		
Upper limit for the converted LE photon RD/MC ratio (at 95% C.L.):1.024		

spectra of a) to d) (by a factor of two). The distributions were therefore fitted with a single Gaussian superimposed over a smooth background. The results of the fit for the numbers of π^0's are given in Table 7.

It follows from these results that the converted HE photon RD to MC ratio is 1.014 ± 0.013 if one takes into account the proper HPC RD to MC bias 1.011 ± 0.004 obtained from the HPC$\times$HPC signals. This ratio agrees well with the double converted photon analysis value 1.020 ± 0.007. The converted LE photon RD to MC ratio is then 0.985 ± 0.028 and the upper limit for the systematic bias of the converted soft photon RD to MC ratio obtained from this test is 1.031 at the 95% C.L. Thus, the two analyses agree and suggest that there is no excess of LE photons from π^0 decays in our kinematic range. A combined upper limit for such an excess derived from both analyses is 1.015 at the 95% C.L. This means that the observed soft photon signal is 4 times greater than the 95% C.L. upper limit resulting from the identity of the π^0 production rates in the RD and MC.

Upper limit for the converted LE photon RD/MC ratio (at 95% C.L.): 1.031
Combined upper limit for the converted LE photon RD/MC ratio: 1.015

These results, in favour of the absence of any non-negligible systematic bias in the current analysis obtained with the π^0 tests, are of high importance due to the fact that the photon production in hadronic Z^0 events is dominated by π^0 decays, as mentioned above. Small admixtures from radiative decays of B^* mesons, η's, Σ^0 baryons and other unstable particles to the overall soft photon production rate are not significant and have been verified not to change the above conclusion on the systematic bias estimations, as discussed in the next section.

6.7 Soft photons from unstable hadrons other than π^0's

The strongest sources of soft photons from unstable hadrons other than π^0's in hadronic Z^0 decays are B^* mesons which have dominant radiative branching ratios and low decay momenta. According to the MC, neutral and charged B^* mesons yield 3.3% and 2.7% of the total soft photon rate in our kinematic range, respectively.

In order to check that there is no bias in the DELPHI MC simulation of soft photons from the B^* meson decays, the B meson admixture in the data under study was varied using the DELPHI B tag [65]. It was found that the signal is stable (within the quoted errors) when varying the B^* photon yield in our kinematic range by a factor of 40, from 0.3% with depleted B^* production (the anti-B tag applied) to 12% with enriched B^* production (the B tag applied), the corresponding results are presented by lines 9 and 10 in Table 3, respectively.

The reason for this stability is easy to understand. Since the observed soft photon signal is of similar strength to the whole relative yield of B^* mesons (both are at about 6% of the total soft photon rate), the DELPHI MC would have to be wrong in the prediction of the B^* production rate by about 100% to allow the signal to come from these mesons. This is completely excluded by the good agreement between the MC and real data for the B^* signal amplitude and its characteristics, studied in [60], from which the discrepancy between the two data sets is deduced to be below 4%.

This fact was used for an independent proof of the statement that an improper simulation of soft photons from the B^* meson decays cannot be responsible for the signal observed. Making use of the B^* photon yield in our kinematic range (6%, see above) and the experimental agreement of the B^* production rate with the simulation, the systematic uncertainty in the total soft photon rate due to B^* photons is established to be below 0.3%. In absolute value, using the total soft photon production rate (4), it is less than $0.05 \times 10^{-3} \gamma$/jet. This uncertainty is quoted in Table 1.

Similar considerations are applicable to other unstable particles. Therefore the yields of η's, Σ^0 baryons and other radiatively decaying hadrons (ω^0, D^* mesons, etc.) to our photon kinematic range were estimated studying the MC data and published results on their total production rates [66–68].

It was found from the MC data that the yield of η mesons to our photon kinematic range is (1.03 ± 0.01)%, the quoted error being statistical. The systematic error of this estimate can be obtained by comparing the MC and experimental η meson total production rates [66]. They agree within 10% [69] which leads to an error in the overall soft photon production rate induced by the η decays of less than 0.1%, or below $0.02 \times 10^{-3} \gamma$/jet. This uncertainty, though relatively small, is included into the software systematic error list quoted in Table 1.

The photon yields from Σ^0 baryons, D^* and other unstable hadrons to our kinematic range are even smaller due to their lower radiative branching ratios and/or higher decay momenta, thus the systematic uncertainties due to them can be neglected.

Finally, the hypothetical situation when the excess photons originate from unstable hadrons which are among Z^0 decay products, but are not incorporated (or not incorporated properly) in the implemented MC event generators, was considered. The method was to calculate the photon p_T^2 spectrum from radiative decays of an a priori unknown unstable (excited) hadron, the excitation energy being varied in a wide range (from 35 to 500 MeV; the mass of the hadron was varied also, from 1 to 5 GeV/c^2, and was found to affect the results very slightly), and to compare the shape of the obtained spectrum with that of the observed excess. In order to account for a diversity of possible kinematic characteristics of the assumed hadron (its energy spectrum and angular distribution relative to a jet) various energy and angular distributions of a large number of unstable hadrons were obtained from the DELPHI MC data and used as templates when generating the re-

sults. Given all the needed input parameters, the photon p_T^2 spectra were calculated using two-body decay phase space formulae.

It was found that only very low excitation energies (below 40 MeV) combined with a narrow angular distribution of the excited hadron are able to produce the exponentially decreasing p_T^2 spectra similar to that of the observed excess (Sect. 5.1). However, no state with such an excitation energy is present in the PDG tables [70]. The nearest candidate for such a state is the B^* (with the excitation energy of 46 MeV), but this state is well incorporated into the DELPHI MC and was directly tested varying the B^* yield as described above.

From these results the conclusion is drawn that no known hadron decaying radiatively can be a source of a viable systematic effect to the observed signal.

7 Conclusions

This analysis shows a significant excess of soft photons close to jet axes in the hadronic decays of the Z^0 collected in the DELPHI experiment at LEP1, as compared to the Parton Shower MC predictions. The photon kinematic range is defined as follows: $0.2 < E_\gamma < 1$ GeV, $p_T < 80$ MeV/c, the p_T being the photon transverse momentum with respect to the parent jet direction. The net excess is measured to be $(1.17 \pm 0.06 \pm 0.27) \times 10^{-3} \gamma$/jet for the data uncorrected for the photon detection efficiency. This value has to be compared to the calculated level of the inner hadronic bremsstrahlung which was expected to be the dominant source of direct soft photons in this kinematic region (but which was not implemented in the standard MC codes used) and is obtained to be $(0.340 \pm 0.001 \pm 0.038) \times 10^{-3} \gamma$/jet. Expressed in terms of the bremsstrahlung rate, the observed signal is $3.4 \pm 0.2 \pm 0.8$.

The various systematic biases capable of producing the excess photons were carefully studied, leading to the conclusion that the origin of the excess cannot be attributed to trivial reasons such as an underestimation of the external bremsstrahlung in the MC events, improper simulation of the soft photon spectra by an event generator or different treatment of the real and MC data by the pattern recognition code. An important point is the good agreement between the MC and real data concerning the production and detection of π^0's when one of the photons of the π^0 decay is soft.

Analogous conclusions can be drawn for the data corrected for the photon detection efficiency: the observed signal rate is found to be $(69.1 \pm 4.5 \pm 15.7) \times 10^{-3} \gamma$/jet, while the inner bremsstrahlung rate is expected to be $(17.10 \pm 0.01 \pm 1.21) \times 10^{-3} \gamma$/jet. Their ratio is then $4.0 \pm 0.3 \pm 1.0$.

The signal amplitudes obtained are close to the anomalous soft photon effects seen earlier in hadronic reactions at high energy and reported in [5–8, 11].
